Information for Authors

Submissions: Submit manuscripts (3 copies) to Editor, *Journal of Applied Physics*, Argonne National Laboratory, Bldg. 203, Room R-127, 9700 South Cass Avenue, P.O. Box 8296, Argonne, IL 60439-8296 (E-mail: jap@anl.gov). Submission implies that the manuscript has not been published previously, and is not currently submitted for publication elsewhere. For detailed information for contributors, visit the above URL.

Publication Charge: To support the cost of wide dissemination of research results through publication of journal pages and production of a database of articles, the author's institution is requested to pay a *page charge* of \$60 per page (with a one-page minimum) and an *article charge* of \$20 per article. For any regular, published article that exceeds 10 journal pages, a mandatory \$150 page charge will be added for each page in excess of 10 pages. For Errata the minimum page charge is \$10, with no article charge.

Reprints: Authors may order reprints with or without covers only in multiples of 50 (with a minimum of 100 in each category) from AIP, Circulation & Fulfillment/Reprints, 500 Sunnyside Blvd., Woodbury, NY 11797-2999; Fax: 516-349-9704; Telephone: 800-344-6909 (U.S. and Canada), or 516-576-2234.

Physics Auxiliary Publication Service (PAPS/E-PAPS): For a nominal fee, authors may deposit material that is supplemental to their published papers. Materials may be on paper or electronic media; examples of appropriate items include data tables, graphs, images, and computer codes. Retrieval instructions are noted in the related published paper. Direct requests to the journal Editor; for additional information, see <http://www.aip.org/epaps/epaps.html>.

Comments: Authors may direct comments to Martin Burke, Director of Editorial Operations, AIP, 500 Sunnyside Blvd., Woodbury, NY 11797-2999. Telephone: 516-576-2406; Fax: 516-576-2223; E-mail: mburke@aip.org.

The *Journal of Applied Physics* is the American Institute of Physics' (AIP) archival journal for significant new results in applied physics. The journal publishes articles that emphasize understanding of the physics underlying modern technology, but distinguished from technology on the one side and pure physics on the other. There are two issues per month. *Applied Physics Reviews* is a series of occasional review articles on similar subjects. The Proceedings of the Annual Conference on Magnetism and Magnetic Materials is a regular feature.

AIP Production: Deborah McHone, *Editorial Supervisor*; Margaret Reilly, *Journal Coordinator*; Janet Panarelli, *Chief Production Editor*; Marilyn Schrage, *Senior Production Editor*; Diane Brzozowski, *Production Editor*

Additional Availability

Online Access: The *Journal of Applied Physics* is available online to print subscribers at no additional charge; for details, please see <http://www.aip.org/ojs/entry.html>. Abstracts of journal articles are available from AIP's SPIN Database, via AIP's PINET Plus Service (<http://www.aip.org/pinet>).

Microform: The *Journal of Applied Physics* is available on microfiche issued at the same frequency as the printed journal, and annually on microfilm. A microform catalog is available from AIP, Circulation & Fulfillment/Single Copy Sales, 500 Sunnyside Blvd., Woodbury, NY 11797-2999; Fax: 516-349-9704; Telephone: 800-344-6908 (U.S. and Canada) or 516-576-2277.

Document Delivery: Copies of journal articles can be ordered for online delivery from the new Articles in Physics online document delivery service (URL: <http://www.aip.org/articles.html>).

Customer Service

Subscription Orders, Renewals, and Address Changes should be addressed to AIP Circulation & Fulfillment Division, 500 Sunnyside Blvd., Woodbury, NY 11797-2999. Allow at least six weeks advance notice. For address changes, please send both old and new addresses and, if possible, include the mailing label from a recent issue.

Claims, Single Copy Replacements, and Back Volumes: Missing issue requests will be honored only if received within six months of publication date (nine months for Australia and Asia). Single copies of a journal may be ordered and back volumes are available in print or microform. Contact AIP Customer Services at 800-344-6902 (U.S. and Canada) or 516-576-2270; Fax: 516-349-9704; E-mail: subs@aip.org.

Reprint Billing: Contact AIP Publication Charge and Reprints/CFD, 500 Sunnyside Blvd., Woodbury, NY 11797-2999; Telephone: 516-576-2230 (800-344-6909); E-mail: pcr@aip.org.

Rights and Permissions

Copying: Single copies of individual articles may be made for private use or research. Authorization is given (as indicated by the Item Fee Code for this publication) to copy articles beyond the use permitted by Sections 107 and 108 of the U.S. Copyright Law, provided the copying fee of \$15 per copy per article is paid to the Copyright Clearance Center, 222 Rosewood Drive, Danvers, MA 01923, USA. Persons desiring to photocopy materials for classroom use should contact the CCC Academic Permissions Service. The Item Fee Code for this publication is 0021-8979/98 \$15.00.

Authorization does not extend to systematic or multiple reproduction, to copying for promotional purposes, to electronic storage or distribution, or to republication in any form. In all such cases, specific written permission from AIP must be obtained.

Other Use: Permission is granted to quote from the journal with the customary acknowledgment of the source. To reprint a figure, table, or other excerpt requires the consent of one of the authors and notification to AIP.

Requests for Permission: Address requests to AIP Office of Rights and Permissions, 500 Sunnyside Blvd., Woodbury, NY 11797-2999; Fax: 516-576-2327; Telephone: 516-576-2268; E-mail: rights@aip.org.

The *Journal of Applied Physics* (ISSN: 0021-8979) is published semimonthly by the American Institute of Physics. Periodicals postage paid at Woodbury, NY 11797, and additional mailing offices. POSTMASTER: Send address changes to *Journal of Applied Physics*, AIP, 500 Sunnyside Blvd., Woodbury, NY 11797-2999.

CONTRIBUTORS TO THE SEVENTH JOINT MAGNETISM AND MAGNETIC MATERIALS-INTERMAG CONFERENCE

The Conference expresses its appreciation to the following organizations for their generous support.

\$2500 and above

Motorola

\$2000 and above

EMTEC Magnetix GmbH, formerly BASF Magnetix GmbH

IBM

TDK Corporation

\$1000 and above

Fuji Photo Film Co., Ltd.

Hewlett-Packard

Hitachi, Ltd. Central Research Laboratory

Imation

Quantum Corporation

Sony Corporation

Toda Kogyo Corp.

\$500-\$999

3M

Applied Magnetix Corporation

Komag

\$250-\$499

Digital Measurement Systems Division of ADE Technologies, Inc.

Eastman Kodak Company

Hyundai Electronics America,

MaxMedia Division

Other Contributions

F. G. Jones Associates, Ltd.

Innovative Instrumentation

PREFACE

The Seventh Joint MMM-Intermag Conference was held 6–9 January 1998, in San Francisco, California at the Hyatt Embarcadero Hotel. The Conference was attended by more than 1,800 registrants, and represents the largest conference on magnetic materials and devices held to date. The high attendance indicates the worldwide research in magnetism and expanding applications for new magnetic materials, particularly in the field of magnetic storage.

An exciting program of 1,143 papers included six invited symposia on Present and Future Tape Systems, Layered Manganites, Electrodeposited Magnetic Nanostructures, Exchange Biasing, High Speed Magnetic Recording, and Advances in Magnetic Imaging. Additional highlights included a panel discussion on the history and future of magnetic storage data and a tutorial session on magnetic imaging sponsored by the IEEE Magnetics Society Education Committee. In the IEEE Awards Session, Dr. Jean-Pierre Lazzari was honored as the recipient of the Johnson Storage Medal, and Professor Stanley Charap was the recipient of the Magnetic Society Achievement Award.

The number of abstract submissions representing 45 countries was an astounding 1,940; which was 50% more than at any previous MMM, Intermag, or Joint MMM-Intermag Conference. The size of the program, however, was limited by hotel space and page allotments in the *Journal of Applied Physics* and the *IEEE Transactions on Magnetics*. By creatively using poster space, up to six parallel oral and six parallel poster sessions were accommodated, and, at times, the meeting rooms were crowded. Publication constraints helped limit the allowed number of accepted abstracts at 1,143, resulting in a rejection rate for contributed abstracts of 41% versus a historical figure of approximately 30–35%. This was a painful, but unavoidable process for everyone. It is difficult to make narrow distinctions between hundreds of diverse abstracts and it emphasizes the importance of carefully written submissions.

The conferences historically have had difficulty with social events, largely as a result of the contrary demands within our community of high expectations and low cost. This year, after considerable soul searching, a nearby restaurant-brewery was selected which happily provided an enjoyable, sudsy evening.

This year, as the Conference took shape, I was impressed with our community's ever-increasing use of electronic document processing and handling. This contrasts with processes used in the "early" days. In 1963, for example, the MMM Program Committee met at IBM-Yorktown Heights, New York. After the Program Committee met, the Program Chairman took the accepted abstracts, drove to a rest stop halfway down the Garden State Parkway, and turned the accepted abstracts over to the Local Chairman who then raced back to Philadelphia to have all the abstracts re-typed manually in a common font. Each abstract was then cut-and-pasted one-by-one to fit into the Program Book before going to the printer! Although technology has changed significantly in 35 years, both conferences were very successful.

Questions have been raised about the usefulness of the Joint Conference. The first Joint MMM-Intermag Conference was held in 1976, and, Dr. Emerson Pugh, the General Chairman, summarized the results as follows: "The real success lies in the opportunity afforded scientists, technologists, and engineers from all over the world to discuss topics of mutual interest, to learn to understand each other better, and thus to return to their own laboratories invigorated and better prepared to contribute to this rapidly evolving field of modern technology." I believe this is still a compelling reason to continue having the Joint Conference, which is supported by attendees surveyed at this Joint Conference by a margin of two to one.

A unique feature of our field is the extent to which its history is documented in the familiar, annual printed issues of two journals. Economic realities combined with technological innovation may lead to changes in our traditions. Future Chairmen will be forced to confront these changes, hopefully with the same wisdom shown by the organizers of the first MMM (1955) and the first Intermag (1963) Conferences. Somehow, a conference held solely on the World Wide Web would seem to be a poor substitute for direct contact and interchange in a beautiful city.

Finally, I extend my sincerest thanks to all the members of the organizing committees who worked continually and diligently for more than a year to make this Joint Conference a success.

Bill Doyle
General Chairman
Seventh Joint MMM-International Magnetics Conference
University of Alabama
Tuscaloosa, Alabama

This issue of the *Journal of Applied Physics* contains 389 papers presented at the Seventh Joint MMM-Intermag Conference. This issue also contains the Table of Contents for the papers which are being published in the *IEEE Transactions on Magnetics*.

xxix Table of Contents for the Papers Appearing in the *IEEE Transactions on Magnetism*

Magnetic Microscopy and Imaging I

- 6217 Time-resolved scanning Kerr microscopy of ferromagnetic structures (invited)
- 6223 Magnetic force microscopy image restoration technique for removing tip dependence
- 6226 Quantification of magnetic force microscopy images using combined electrostatic and magnetostatic imaging
- 6229 Magnetic force microscopy using nonoptical piezoelectric quartz tuning fork detection design with applications to magnetic recording studies
- 6232 Kerr effect enhancement by photon tunneling and possible application to a new scanning probe magnetic microscope
- 6235 Design and construction of a sensitive nuclear magnetic resonance force microscope

M. R. Freeman, W. K. Hiebert, A. Stankiewicz

Jian-Gang Zhu, Xiangdong Lin, Rick C. Shi, Yansheng Luo

R. D. Gomez, A. O. Pak, A. J. Anderson, E. R. Burke, A. J. Leyendecker, I. D. Mayergoz

M. Todorovic, S. Schultz

A. Kikitsu, C. M. Falco, M. Mansuripur

T. A. Barrett, C. R. Miers, H. A. Sommer, K. Mochizuki, J. T. Markert

Nanocomposite and Film Hard Magnets

- 6238 Exchange-spring behavior in epitaxial hard/soft magnetic bilayer films
- 6241 Magnetization reversal of Nd(Dy)-Fe-B thin films on Si(111) or Ta/Si(111)
- 6244 Phase formation and magnetic properties of Co-rare earth magnetic films
- 6247 High coercivity SmCo based films made by pulsed laser deposition
- 6250 Mechanism of composition change in sputter deposition of barium ferrite films with sputtering gas pressure
- 6253 Magnetic and structural properties of high coercivity Sm(Co, Ni, Cu) sputtered thin films
- 6256 Mechanically alloyed nanocomposite magnets (invited)
- 6262 Micromagnetic simulation of magnetizability of nanocomposite Nd-Fe-B magnets
- 6265 Thick Fe₃B/Nd₂Fe₁₄B nanocomposite permanent magnet flakes prepared by slow quenching
- 6268 Analysis of magnetic behavior of exchange-enhanced SmFeCo magnets
- 6271 The effect of boron and rare earth contents on the magnetic properties of La and Cr substituted α -Fe/R₂Fe₁₄B-type nanocomposites
- 6274 Anomalous high-temperature coercivities in hard nanocomposite alloys
- 6277 Magnetic interactions in Fe-Ba hexaferrite nanocomposite materials

J. S. Jiang, Eric E. Fullerton, M. Grimsditch, C. H. Sowers, S. D. Bader

J. L. Tsai, T. S. Chin, E. Y. Huang, S. K. Chen

Y. Liu, Richard A. Thomas, S. S. Malhotra, Z. S. Shan, S. H. Liou, D. J. Sellmyer

F. J. Cadieu, R. Rani, X. R. Qian, Li Chen

E. Suzuki, Y. Hoshi, M. Naoe

C. Prados, G. C. Hadjipanayis

P. G. McCormick, W. F. Miao, P. A. I. Smith, J. Ding, R. Street
Thomas Schrefl, Josef Fidler

H. Kanekiyo, S. Hirosawa

M. Dahlgren, R. Grössinger, D. R. Cornejo, F. P. Missell

W. C. Chang, D. Y. Chiou, S. H. Wu, B. M. Ma, Q. Chen, C. O. Bounds

L. H. Lewis, J.-Y. Wang, D. O. Welch, V. Panchanathan

M. I. Montero, F. Cebollada, M. P. Morales, J. M. González, A. Hernando

Surface and Interface Effects

- 6280 Infrared studies of magnetic surface modes on antiferromagnets (invited)

R. E. Camley, M. R. F. Jensen, S. A. Feiven, T. J. Parker

(Continued)

- 6284 Strain induced alteration of the gadolinium surface state
- 6287 Effect of surface roughness on magnetization reversal of Co films on plasma-etched Si(100) substrates
- 6290 Exploring magnetic roughness in CoFe thin films
- 6293 Soft x-ray resonant magnetic reflectivity study of thin films and multilayers
- 6296 Dependence of anti-Stokes/Stokes intensity ratios on substrate optical properties for Brillouin light scattering from ultrathin iron films

Critical Phenomena, Spin Glasses, and Frustration

- 6299 Magnetic phase diagrams of holmium determined from magnetoresistance measurements
- 6302 Magnetostatic critical point phenomena of ErGa garnet
- 6305 Monte Carlo investigation of the eight-state Potts model on quasiperiodic tilings
- 6308 Exact renormalization group equation for systems of arbitrary symmetry free of redundant operators
- 6311 Random-exchange and random-field Ising model-like behaviors in $\text{Fe}_{0.48}\text{Zn}_{0.52}\text{F}_2$
- 6314 Magnetic structures of the triangular lattice magnets $\text{AFe}(\text{SO}_4)_2$ (A=K, Rb, Cs)
- 6317 Phase transition and phase diagram of the J_1-J_2 Heisenberg model on a simple cubic lattice
- 6320 Spin fluctuations and thermal expansion of $\text{La}(\text{Ni}_x\text{Al}_{1-x})_{13}$ amorphous alloys
- 6323 Magnetic relaxation in $\text{Ga}_{0.6}\text{Mo}_2\text{S}_4$ spinel

Nanocrystalline and Amorphous Soft Materials

- 6326 New bulk amorphous Fe-(Co,Ni)-M-B (M=Zr,Hf,Nb,Ta,Mo,W) alloys with good soft magnetic properties
- 6329 Influence of Si addition on thermal stability and soft magnetic properties for Fe-Al-Ga-P-C-B glassy alloys
- 6332 Application of nanocrystalline soft magnetic Fe-M-B (M=Zr, Nb) alloys to choke coils
- 6335 Soft magnetic properties and structures of nanocrystalline Fe-Al-Si-B-Cu-Nb alloy ribbons
- 6338 Compositional dependence of the effective magnetic anisotropy in nanocrystalline Fe-Zr-B-(Cu) alloys
- 6341 Approach to the magnetic saturation in nanocrystalline ferromagnets in the random anisotropy model

Numerical Methods

- 6344 Multigrid methods for computation of magnetostatic fields in magnetic recording problems

- C. Waldfried, D. N. McIlroy, T. McAvoy, D. Welipitiya, P. A. Dowben, E. Vescovo
- M. Li, Y.-P. Zhao, G.-C. Wang, H.-G. Min

G. R. Aranda, J. González, K. Kulakowski

Igor Tsukerman, Alexander Plaks, H. Neal Bertram

- 6347 Modified scalar potential solution for three-dimensional magnetostatic problems
- 6350 Numerical simulation of the magnetization structures in thin polycrystalline films with the random anisotropy and intergrain exchange
- 6353 Finite element analysis of the influence of a fatigue crack on magnetic properties of steel
- 6356 Magnetohydrodynamic calculation for free surfaces
- 6359 Differential Preisach model for the description of dynamic magnetization processes
- 6362 Influence of the permanent magnet overhang on the performance of the brushless dc motor
- 6365 Optimization of coils for detecting initial rotor position in permanent magnet synchronous motor
- 6368 Temperature analysis of induction motors using a hybrid thermal model with distributed heat sources
- 6371 Bifurcation phenomena and chaotic attractors in a six-dimensional nonlinear system

Symposium on Layered Manganites

- 6374 Two-dimensional ferromagnetic correlations above T_C in the naturally layered CMR manganite $\text{La}_{2-2x}\text{Sr}_{1+2x}\text{Mn}_2\text{O}_7$ ($x=0.3-0.4$) (invited)
- 6379 Chemistry of naturally layered manganites (invited)
- 6385 Role of intergrowths in the properties of naturally layered manganite single crystals (invited)

Rare Earth and Boride Hard Magnets

- 6390 The development of high performance Nd-Fe-Co-Ga-B die upset magnets
- 6393 Plastic deformation modeling of die-upset process for magnequench NdFeB magnets
- 6396 Microstructural analysis of strip cast Nd-Fe-B alloys for high $(\text{BH})_{\text{max}}$ magnets
- 6399 Extension of the primary solidification region of $\text{Nd}_2\text{Fe}_{14}\text{B}$ by levitation of undercooled melts
- 6402 High performance Nd-Fe-B sintered magnets made by the wet process
- 6405 Hydrogen absorption and desorption behavior in Pr-Fe-B type alloys
- 6408 Coercivity of sintered $\text{Nd}(\text{Fe}_{0.92-x}\text{Ga}_xB_{0.08})_{5.5}$ permanent magnets
- 6411 The origin and interpretation of fine scale magnetic contrast in magnetic force microscopy: A study using single-crystal NdFeB and a range of magnetic force microscopy tips
- 6414 Off-axis electron holographic mapping of magnetic domains in $\text{Nd}_2\text{Fe}_{14}\text{B}$
- 6417 Improvement of protective coating on Nd-Fe-B magnet by pulse nickel plating
- 6420 A pump with flat-ring-shaped magnets

Computational Micromagnetics

- 6489 Anisotropy design in magnetic media: A micromagnetics study
- 6491 A variational approach to exchange energy calculations in micromagnetics

J. H. Kaufman, T. Koehler, A. Moser, D. Weller, B. Jones

M. J. Donahue

- 6494 Hysteresis loop areas in kinetic Ising models: Effects of the switching mechanism
- 6497 Domain-wall motion in random potential and hysteresis modeling
- 6500 The field-space perspective on hysteresis in uniaxial ferromagnets
- 6503 Micromagnetic localization
- 6506 Computational micromagnetic investigation of magnetization reversal in Nd-Fe-B nanocomposite magnets
- 6509 Influence of the system parameters on the non-Arrhenius magnetic relaxation of systems having distributed properties

Spin-Dependent Tunneling I

- 6512 Voltage dependence of magnetoresistance in spin dependent tunneling junctions
- 6515 Bias voltage and temperature dependence of magnetotunneling effect
- 6518 Finite bias spin dependent tunneling: A nonequilibrium Green's function approach
- 6521 Spin-dependent tunneling in epitaxial systems: Band dependence of conductance
- 6524 Anomalous behavior of temperature and bias-voltage dependence of tunnel-type giant magnetoresistance in insulating granular systems

New Materials and Magnetic Semiconductors

- 6527 High perpendicular anisotropy and magneto-optical activities in ordered Co₃Pt alloy films
- 6530 Thermopower studies of percolating magnetic metallic nanostructures
- 6533 Structural and magnetic properties of Fe_xSe_y thin films during their selenization process
- 6536 Magnetic behavior of the new low- T_c phase of SrRuO₃
- 6539 Growth and characterization of epitaxial thin films of conductive ferromagnetic oxide SrRuO₃
- 6542 A field induced ferromagnetic-like transition below 2.8 K in Li₂CuO₂: An experimental and theoretical study
- 6545 Magneto-optic study of Ni-based diluted magnetic semiconductors
- 6548 Magneto-optic effect of the ferromagnetic diluted magnetic semiconductor Ga_{1-x}Mn_xAs
- 6551 Hall effect and magnetic properties of III-V based (Ga_{1-x}Mn_x)As/AlAs magnetic semiconductor superlattices
- 6554 Long-range antiferromagnetic couplings in [ZnTe|MnTe] superlattices
- 6557 Magnetic measurements on the III-VI diluted magnetic semiconductor Ga_{1-x}Mn_xSe
- 6560 Second harmonic spectroscopy and control of domain size in antiferromagnetic YMnO₃

- S. Y. Wu, Y. C. Chang, K. C. Lee, W.-H. Li
- W. Schnelle, R. W. Henn, Th. Gulden, R. K. Kremer, A. Simon

- 7324 H - T phase diagram for the giant magnetic flux jumps in low temperature superconductors and high temperature superconductors
- 7327 Magnetic memory effect in $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}/(\text{BiDy})_3(\text{FeGa})_5\text{O}_{12}$ heterostructures
- 7330 Spin wave scattering and intermode transitions induced by the magnetic vortex lattice in the ferrite-high-temperature superconductor film structure

Advances in Magnetic Force Microscopy

- 7333 Magnetic dissipation force microscopy studies of magnetic materials (invited)

Fundamental Aspects of CMR Materials

- 7339 Long wavelength spin dynamics in $\text{La}_{0.53}\text{Ca}_{0.47}\text{MnO}_3$
- 7342 Spin dynamics of strongly doped $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$
- 7345 Tilted antiferromagnetic ordering of Mn in $\text{Nd}_{0.62}\text{Ca}_{0.38}\text{MnO}_3$
- 7348 Magnetic correlations in the bilayer manganite $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$
- 7351 The complex magnetic behavior and the role of dynamic structural fluctuations in $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$ crystals
- 7354 Lattice effects in ferromagnetic manganite perovskites
- 7357 Isotope effect and T_c in manganites and high T_c oxides
- 7360 A mean field theory of magnets with competing double exchange and superexchange interactions
- 7363 Composite polaron mechanism for colossal magnetoresistance in perovskite manganites
- 7366 Tunneling evidence of half-metallicity in epitaxial films of ferromagnetic perovskite manganites and ferrimagnetic magnetite
- 7369 Metal-insulator transition induced by ^{16}O - ^{18}O oxygen isotope exchange in colossal negative magnetoresistance manganites

Spin Glasses and Frustrated Systems

- 7372 Magnetic susceptibility of Fe/Cu multilayers: Ferromagnetic, antiferromagnetic, and spin-glass phases
- 7375 Origin of magnetic anomalies in the spin glass system, $\text{La}_{0.85}\text{Sr}_{0.15}\text{CoO}_3$
- 7378 Canted antiferromagnetism and spin glasslike behavior in a family of two-dimensional organic/inorganic nanocomposites
- 7381 Magnetic and structural properties of $\text{PrCo}_{3-x}\text{Si}_x$ compounds
- 7384 Frustration in the paramagnetic phase of spin-density-wave CrFeV alloys
- 7387 A new paradigm for two-dimensional spin liquids
- 7390 Calculation of the energy barriers in strongly interacting many-particle systems

PART I

MAGNETIC MULTILAYERS

Determination of the Copper Layer Thickness in Spin Valves by Grazing Incidence X-Ray Fluorescence — <i>T. P. A. Hase, B. K. Tanner, P. Ryan, C. H. Marrows, and B. J. Hickey</i>	
Influence of the Top and Bottom Interface on Perpendicular Magnetic Anisotropy in Tb-Fe-Ag Multilayers — <i>O. Marks, T. Ruckert, J. Tappert, W. Keune, W.-S. Kim, W. Kleemann, and J. Voiron</i>	
NiO/ α -Fe ₂ O ₃ Multilayers Prepared by PLD: A Model System for Magnetic Study of Interdiffusion — <i>N. Keller, M. Guyot, A. Das, M. Porte, and R. Krishnan</i>	
Correlation Between Evolving Magnetic and Morphological Properties in Magnetic Multilayers — <i>S. A. Doherty, J.-G. Zhu, M. Dugas, S. Anderson, and J. Tersteeg</i>	
Spin Valve Structures on NiO Pinning Layers — <i>C. Cowache, B. Dieny, S. Auffret, M. Cartier, R. H. Taylor, R. O'Barr, and S. Y. Yamamoto</i>	
FMR and Magnetization Study of NiFe/Ag/CoNi Trilayer Film — <i>A. R. Koymen, L. R. Tagirov, R. T. Gilmutdinov, C. Topaci, C. Birlikseven, H. Z. Durusoy, and B. Aktas</i>	
Highly Localized Surface Modes in Epitaxial W/Ni/W Films — <i>G. Suran, J. Rothman, and C. Meyer</i>	
Iron and Nickel Surface and Interface Anisotropies — <i>R. Skomski, D. Sander, C. Schmidhals, A. Enders, and J. Kirschner</i>	
Second Harmonic Generation Study of Quantum Well States and Interdiffusion in a Co/Rh Multilayer — <i>F. Manders, K. J. Veenstra, A. Kirilyuk, T. Rasing, H. A. M. van den Berg, and N. Persat</i>	
Role of Magnetoelastic Anisotropy in Ni/Pt Multilayer Films — <i>Y.-S. Kim and S.-C. Shin</i>	

- Strong Anti-Ferromagnetic Coupling in τ MnAl/Co Perpendicular Magnetic Superlattices on GaAs — C. Bruynseraede, G. Lauhoff, J. A. C. Bland, G. Strijkers, J. De Boeck, and G. Borghs
- Competition Between Direct Exchange and Indirect RKKY Coupling in Fe/V(001) Superlattices — G. R. Harp, M. M. Schwickert, M. A. Tomaz, T. Lin, D. Lederman, E. Mayo, and W. L. O'Brien
- Growth of Giant Magnetoresistive Spin Valves with Strong Exchange Bias Field — G. Choe, A. Tsoukatos, and S. Gupta
- Preferred Crystal Orientation of NiFe Underlayers and its Effect on Magnetostriction of Co/Cu/Co Thin Films — T. Yeh, J. M. Sivertsen, and C.-L. Lin
- Magnetic Anisotropies of Fe_nV_m(001) Superlattices Determined by Ferromagnetic Resonance — A. N. Anisimov, W. Platow, P. Pouloupoulos, M. Farle, K. Baberschke, P. Isberg, P. Granberg, and R. Wäppling
- Magnetic Anisotropy and Reorientation in Co/Rh Superlattices — X. Ying, K. V. Rao, P. J. Jensen, and J. J. Xu
- Magnetic and Transport Properties of Sputter Deposited Ni/Co Multilayers — R. J. Pollard, S. E. McCartney, and R. Atkinson
- Thin Soft Sendust Film Laminated CoPt Hard Films — S. S. Xue, J. F. Dolejsi, and P. J. Ryan
- Spin Waves and Interlayer Coupling in CoFe/Mn/CoFe Structures — M. Chirita, G. Robins, R. L. Stamps, R. Sooryakumar, M. E. Filipkowski, C. J. Gutierrez, and G. A. Prinz
- First Principles Calculations of the Energetics of Co/Cu(111) Multilayers — X. Wang and C. L. Fu
- Superlattices of III-V Semiconductor and Heterogeneous Magnetic Layers for CPP Magnetotransport — J. De Boeck, H. Akinaga, C. Bruynseraede, H. Bender, and G. Borghs

GIANT MAGNETORESISTANCE AND TRANSPORT

- Stress Effects on the Magnetic Properties of FeMn and NiMn Spin Valves — E. Linville, D. Han, J. Judy, J. Sivertson, and S. Mao
- Time and Temperature Dependence of High Thermal Stability in NiO/Co/Cu/Co/M Spin Valves — R. D. McMichael, P. J. Chen, and W. F. Egelhoff, Jr.
- Magnetoresistance Due to Domain Walls in Micron Scale Fe Wires with Stripe Domains — A. D. Kent, U. Ruediger, J. Yu, S. Zhang, P. M. Levy, Y. Zhong, and S. S. P. Parkin
- Anisotropic Magnetoresistance as a Probe of Magnetization Reversal in Individual Nano-sized Nickel Wires — J.-E. Wegrowe, S. E. Gilbert, D. Kelly, B. Doudin, and J.-P. Ansermet
- Temperature Dependence of Interlayer Coupling in Fe/Si Superlattices — Y. Endo, O. Kitakami, and Y. Shimada
- Mossbauer Studies of Fe-Pb-O Granular Films with Enhanced Tunneling Magnetoresistance Effect — J.-H. Hsu, Y.H. Huang, P. K. Tseng, and D. E. Chen
- Magnetic Microstructures from Magnetic Force Microscopy and Monte Carlo Simulation in CoFe-Ag-Cu Granular Films — V. Franco, X. Batlle, A. Valencia, A. Labarta, K. O'Grady, and M.L. Watson
- GMR in DC Magnetron Sputtered Ni₈₁Fe₁₉/Cu Multilayers — M. Mao, C. Cerjan, M. Gibbons, B. Law, F. Grabner, S. P. Vernon, and M. Wall
- Highly Field Sensitive and Thermally Stable DC Magnetron Sputtered Soft Ni₈₁Fe₁₉/Cu Multilayers — Y. Huai, M. Tan, and R. Rottmayer
- Improvement of GMR Characteristics in [Ni₈₁Fe₁₉/Cu] Multilayers by Interfacial Modulation Technique using Kr Ions — Y. Miyamoto, K. Watanabe, K. Nishimura, S. Nakagawa, and M. Naoe
- CPP Giant Magnetoresistance of NiFeCo/Cu/CoFe/Cu Multilayers — K. Bussmann, S. F. Cheng, G. A. Prinz, Y. Hu, R. Gutmann, D. Wang, R. Beech, and J. Zhu
- First-Principles Based Semi-Classical Model for Transport in Magnetic Layered Structures — W. H. Butler, X.-G. Zhang, and J. M. MacLaren
- GMR in Magnetic Multilayers from a First Principles Band Structure Kubo-Greenwood Approach — F. Rao and A. J. Freeman
- A Superlattice Effect in the Resistivity of Multilayers — T.-S. Choy, J. Chen, and S. Hershfield
- Influence of Impurity Gas in the Sputtering Atmosphere on the Microstructure and the GMR in Co/Cu Multilayers — S. Miura, D. Takahashi, M. Tsunoda, and M. Takahashi
- Giant Magnetoresistance of Current-Perpendicular Exchange-Biased Spin Valves of Co/Cu — A. C. Reilly, W.-C. Chiang, W. Park, S. Y. Hsu, R. Loloee, S. Steenwyk, W. P. Pratt, Jr., and J. Bass
- Comparison of Computed Amplitudes of Magnetoresistance in Spin-Valve Structures with Wafer Probe Measurements — B. Dieny, L. G. Peireira, R. H. Taylor, and S. Y. Yamamoto
- Process Monitoring of Spin-Valve GMR Deposition — J. C. S. Kools, A. P. Paranjpe, P. V. Schwartz, R. Bubber, B. Bergner, W. Kula, and T. G. S. M. Rijks
- Specular Reflection in Spin Valves Bounded by NiO Layers — H. J. M. Swagten, G. J. Strijkers, R. H. J. N. Bitter, W. J. M. de Jonge, and J. C. S. Kools
- Thermal Stability of Spin Valve with NiO/a-Fe₂O₃ Bilayer Antiferromagnets — J. Fujikata, K. Hayashi, M. Saito, and M. Nakada

- Effect of Microstructure on Resistivity and GMR Ratio in Ion Beam Deposited Spin Valves — *W. E. Bailey, D. Guarisco, and S. X. Wang*
- CoFe/IrMn Spin-Valves Prepared on Cu Islands — *T. Umemoto, A. Maeda, S. Oikawa, K. Yoshioka, S. Takahashi, T. Tanuma, M. Kume, and K. Shibata*

MAGNETIC NANOSTRUCTURES

- Reversible Electrodeposition of Ultrathin Magnetic Co and Films — *W. Schindler, T. Koop, D. Hofmann, and J. Kirschner*
- Magnetic and Transport Properties of Electrodeposited Nanostructured Nanowires — *B. Doudin, J. E. Wegrowe, S. E. Gilbert, V. Scarani, D. Kelly, J. P. Meier, and J.-P. Ansermet*
- Magnetization Reversal in Individual Nanoparticles Macroscopic Quantum Tunneling of Magnetization — *W. Wernsdorfer, E. B. Orozco, B. Barbara, A. Benoit, D. Mailly, N. Demoncey, H. Pascard, O. Kubo, and H. Nakano*
- Single Particle Measurement Showing Agreement with the Model of Uniform Rotation — *E. B. Orozco, W. Wernsdorfer, B. Barbara, K. Hasselbach, A. Benoit, and D. Mailly*
- The Magnetic Properties of Annealed Graphite-Coated Ni and Co Nanocrystals — *J. A. Block, K. Parvin, J. L. Alpers, T. Sezen, R. LaDuca, J. J. Host, and V. P. Dravid*
- Size and Interaction Effects in the Magnetization Reversal in SmCo₅ Nanoparticles — *S. A. Majetich, K. M. Chowdary, and E. M. Kirkpatrick*
- Organizing Nanometer-Scale Magnets with Bacterial Threads — *C. J. Smith, M. Field, C. J. Coakley, D. D. Awschalom, N. H. Mendelson, E. L. Mayes, S. A. Davis, and S. Mann*
- Magnetic Aftereffect in Quasi-1D Amorphous Ferromagnetic Nanocolumns — *J.-P. Nozières, D. Givord, J. C. Toussaint, B. Kevorkian, M. Ghidini, and B. Gervais*
- Magnetic Properties of Au_{1-x}Fe_x Nanowires — *J. Jorritsma and J. A. Mydosh*
- End Domain States and Magnetization Reversal in Submicron Magnetic Structures — *J. Shi, T. Zhu, M. Durlam, E. Chen, S. Tehrani, Y. F. Zheng, and J.-G. Zhu*
- Shape Dependence of the Switching Field in Small Structures — *S. T. Chui*
- Dynamics of Magnetization Reversal in a 20x4 mm Permalloy Microstructure — *A. Stankiewicz, W. K. Hiebert, G. E. Ballentine, K. W. Marsh, and M. R. Freeman*
- Reversal Mechanism of Submicron Patterned CoNi/Pt Multilayers — *M. A. M. Haast, J. R. Schuurhuis, L. Abelmann, J. C. Lodder, and T. J. Popma*
- Magnetization Reversal in Nanostructured Co/Pt Multilayer Dots and Films — *M. Thielen, S. Kirsch, H. Weinforth, A. Carl, and E. F. Wassermann*
- Domain Structures Supported by Micron-Sized Patterned Co/Cu Multilayers with AF and FM Coupling — *P. R. Aitchison, J. N. Chapman, K. J. Kirk, D. B. Jardine, and J. E. Evetts*
- The Relationship Between Structure and Magnetic Properties in Nanostructured FePd Ferromagnets — *H. Okumura, W. A. Soffa, T. J. Klemmer, and J. A. Barnard*
- Chemical Synthesis of Nanostructured Cobalt at Elevated Temperatures — *D. L. Leslie-Pelecky, M. Bonder, T. Martin, E. M. Kirkpatrick, X. Q. Zhang, S.-H. Kim, and R. D. Rieke*
- Magnetic and Magneto-transport Properties of Novel Nanostructured Networks — *K. Liu and C. L. Chien*
- Temperature Dependence of the Coercivity of Fe Films Sputtered On Nanochannel Alumina — *A. Butera, J. L. Weston, and J. A. Barnard*
- Magnetization Reversal in (CoNi/Pt)₆ Dots Connected to a Large Area through Submicron Wide Channels — *F. Fournel, Y. Chen, F. Carcenac, N. Essaidi, H. Launois, V. Kottler, and C. Chappert*
- Paramagnetic-Superparamagnetic Transition in Molecular Sieve Supported Antiferromagnetic Particles — *F. J. Lazaro, A. Lopez, A. Larrea, Q. A. Pankhurst, J. M. Lopez Nieto, and A. Corma*
- Modifications of the Effective Surface and Crystalline Anisotropies of Ag/Fe/Ag-(001)-Layers by Ion Implantation — *D. Kurowski, J. Pflaum, K. Brand, J. Pelzl, and P. Grünberg*
- Temperature Dependence of the Interface Interactions on Fe/Cr Studied by Ferromagnetic Resonance and SQUID — *J. Pflaum, J. Pelzl, P. Bödeker, H. Zabel, Z. Frait, and M. Marysko*
- Evidence for Domain-Condensation near the Ferromagnetic to Paramagnetic Transition in Perpendicularly Magnetized, Ultrathin Fe/2 ML Ni/W(110) Films — *C. S. Arnold and D. Venus*
- Electric Field Effects on Magnetic and Optical Properties of MnAs/GaAs(001) Thin Films — *T. Shin, M. C. Park, Y. Park, G. M. Rothberg, M. Tanaka, and J. P. Harbison*
- NMR Studies of Sputtered CoFe Alloy Thin Films — *T. Thomson, P. C. Riedi, C. L. Platt, and A. E. Berkowitz*
- Magnetic Dipole Model of Magnetization-Induced Surface Second Harmonic Generation — *V. L. Brudny, W. L. Mochán, B. S. Mendoza, A. V. Petukhov, and T. Rasing*
- Effect of Dipolar Interactions in Magnetic Thin Films — *C. Santamaria and H. T. Diep*
- Hybrid Ferromagnet-Semiconductor Nonvolatile Gate — *M. Johnson, B. R. Bennet, M. J. Yang, M. M. Miller, and B. V. Shanabrook*

- Pseudo Spin Valve MRAM Cells with Sub-Micrometer Critical Dimension — *B. A. Everitt, A. V. Pohm, R. S. Beech, A. Fink, and J. M. Daughton*
- Characteristics of AP Bias in Spin Valve Memory Elements — *J.-G. Zhu and Y. Zheng*
- The Effect of End Edge Shape on the Performance of Pseudo-Spin Valve Memories — *J. Gadbois, J.-G. Zhu, W. Vavra, and A. Hurst*
- A New Multilayered Structure for Multilevel Magnetoresistive Random Access Memory (MRAM) Cell — *W.-C. Jeong, B.-I. Lee, and S.-K. Joo*
- Nucleation of Periodic Domain Structure in Micro-Fabricated Spin valve Strip Pattern — *K. Matsuyama, H. Asada, Y. Hosokawa, and K. Taniguchi*
- Generation, Gyroscopic Dynamics and Collisions of the Vertical Bloch Lines in the Orthoferrites — *M. V. Chetkin and Yu. N. Kurbatova*
- Memory Element Based on a Layered Galvanomagnetic Structure — *Y. V. Timoshkov, A. L. Danilyuk, I. S. Molchan, T. I. Orechovskaya, and V. I. Kurmashev*

PATTERNED AND HYBRID MAGNETIC MATERIALS

- Magnetic Coupling in Self-Organized Narrow-Spaced Fe Nanowire Arrays — *A. Sugawara, D. Streblechenko, M. McCartney, and M. R. Scheinfein*
- Magnetic Singularities in Self-Organized Epitaxial Cobalt Structures — *M. Demand, M. Hehn, S. Cherifi, K. Cherifi, K. Ounadjela, and R. L. Stamps*
- Fabrication of Large Area Nanostructured Magnets by Interferometric Lithography — *M. Farhoud, M. Hwang, H. I. Smith, M. L. Schattenburg, J. M. Bae, K. Youcef-Toumi, and C. A. Ross*
- Magnetization Reversal in Submicron Ferromagnetic Dots and Antidots Arrays — *Y. Otani, S. G. Kim, T. Kohda, K. Fukamichi, O. Kitakami, and Y. Shimada*
- Giant Positive Magnetoresistance in Arrays of Semi-metallic Bismuth Nanowires — *K. Liu, C. L. Chien, P. C. Searson, K. Yu-Zhang*
- Magnetic and Transport Properties of Sub-Micron Ferromagnetic Wires — *Y. Otani, S. G. Kim, K. Fukamichi, O. Kitakami, and Y. Shimada*
- Size Dependence of the Magnetization Vector Reversal Processes in Epitaxial Fe(001) Microstripes — *E. Ahmad, J. A. C. Bland, and E. Gu*
- Magnetization Switching Behavior in Nanostructured Nife/Co/Cu/Co Spin-Valve — *H. Asada, K. Matsuyama, Y. Hosokawa, and K. Taniguchi*
- Magnetic Anisotropy in Arrays of Nanometer-Scale Iron Particles — *S. Wirth, J. J. Heremans, S. Von Molnár, M. Field, K. L. Chapman, A. C. Gossard, and D. D. Awschalom*
- Highly Homogeneous Nanoparticulate Fe Films Prepared by Laser Ablation — *J. M. González, M. I. Montero, L. Vásquez, J. A. Martín Gago, D. Givord, C. De Julián, and K. O'Grady*
- Magnetic Properties of a Series of Ferrite Nanoparticles Synthesized in Reverse Micelles — *C. T. Seip, E. E. Carpenter, C. J. O'Connor, V. T. John, and S. Li*
- High Coercivity in Heterogeneous Co-Rich Co-Ag Very Thin Films — *A. Butera, T. J. Klemmer, K. Minor, H. S. Cho, and J. A. Barnard*
- Superparamagnetism of Granular Fe-MgF₂ Films — *T. Furubayashi and I. Nakatani*
- Magnetization and Coercivity of Antiferromagnetic Particles — *K. N. Trohidou, X. Zianni, and J. A. Blackman*
- Magnetotransport and Magnetism in Granular EuS-Co and EuS-Ag Nanocomposites Prepared by Mechanical Alloying — *C. E. O'Connor, L. Feng, C. T. Seip, and J. Tang*
- Magnetization Curve for Iron-Nitride Fine Particles System with Random Anisotropy — *H. Mamiya and I. Nakatani*
- Magnetic Properties of Ball Milled Fe-40Al at .% Alloys — *X. Amils, J. Nogués, S. Suriñach, M. D. Baró, and J. S. Muñoz*
- Structural, Electrical, and Magnetic Properties of Co_xC_{1-x} Granular Films — *H. Weinforth, C. Somsen, B. Rellinghaus, A. Carl, E. F. Wassermann, and D. Weller*
- Magnetic and Magneto-Transport Properties of Metastable Gd_xNb_{1-x} Alloys — *R. L. Sommer, J. Q. Xiao, and C. L. Chien*
- Algorithm for the Computation of the FC and ZFC Magnetization Curves for Nanoparticle Systems — *C. Papusoi, Jr., A. Stancu, C. Papusoi, J.L. Dormann, M. Nogués, and E. Tronc*
- Preparation of Iron Nanoparticles by Reduction of Acicular β -FeOOH Particles — *M. Chen, B. Tang, and D. E. Nikles*
- Fabrication and Properties of Microforged Ferromagnetic Nanoflakes — *R. M Walser and W. Kang*

SOFT MAGNETIC MATERIALS AND DOMAINS

- Domain Walls and Magnetic Properties of Very Thin Permalloy Films for Magnetoresistive Sensors — *M. A. Akhter, D. J. Mapps, Y. Q. Ma, A. K. Petford-Long, and R. Doole*
- Characteristics of Stripe Domains in FeTaN Films Observed by Magnetic Force Microscopy — *H. S. Cho, V. R. Inturi, J. A. Barnard, and H. Fujiwara*

- Magnetic Domains and Transverse Induced Anisotropy in Magnetically Soft CoFeB Amorphous Thin Films — *D. García, J. L. Muñoz, G. Kuryandskaya, M. Vázquez, M. Ali, and M. R. J. Gibbs*
- Incoherent Magnetization Reversal Process in Discontinuous Fe₅₀Co₅₀/Ag Multilayer Thin Films — *P. C. Kuo, Y. D. Yao, J. W. Chen, and H. C. Chiu*
- Giant Magnetoimpedance in CoFeBSi Wires and Polycrystalline Ferrites — *E. Carrasco, K. L. García, and R. Valenzuela*
- The Effects of Axial DC Field on Magnetoimpedance: Circumferential Domain Wall Damping — *K. L. García and R. Valenzuela*
- Surface Magnetic Domain Observation on Thin-Gauged 3% Si-Fe Sheets by using Scanning Electron Microscopy with Polarization Analysis (SEMPA) — *Y. Lee, A. R. Koymen, N. H. Heo, J. G. Na, and J. S. Woo*
- Dynamic Preisach Model and Energy Dissipation in Soft Magnetic Materials — *L. R. Dupré, G. Bertotti, and J. A. A. Melkebeek*
- Determination of Barkhausen Signal Scaling from Higher Order Spectral Analysis — *J. R. Petta, M. B. Weissman, and G. Durin*
- Identification of Microstructure Effects in Magnetic Loss Behaviour of 3.2% SiFe N.O. Electrical Steels by Means of Statistical Power Loss Model — *G. Bán, P. E. Di Nunzio, S. Cicalè, and T. Belgrand*
- Dynamic Effects Driven by Thermal Activation in the Magnetization of Nanocrystalline Soft Magnetic Materials — *V. Basso, M. LoBue, C. Beatrice, P. Tiberto, and G. Bertotti*
- Influence of Surface Roughness on Magnetic Properties of Fe-Si-B Amorphous Alloys — *K. Matsuki, F. Kogiku, and N. Morito*
- Magnetic Properties of 6.5% Silicon Steel Sheets Under PWM Voltage Excitation — *M. Namikawa, H. Ninomiya, Y. Tanaka, and Y. Takada*
- Comparison of Transformer Loss Prediction from Computed and Measured Flux Density Distribution — *A. J. Moses* ...
- Apparent Core Losses and Core Losses in Five-Limb Amorphous Transformer of 160 kVA — *S. Sieradzki, R. Rygal, and M. Soinski*
- Reduction of Inrush Current in Single-Phase Transformer using Virtual Air Gap Technique — *V. Molcrette, J.-L. Kotny, J.-P. Swan, and J.-F. Brudny*

MAGNETIC EFFECTS AND MODELING

- Shifted Magnetization Curves in Ultrathin Co Films on Stepped Cu(100) — *A. Rettori, L. Trallori, M. G. Pini, C. Stamm, C. Wüsch, S. Egger, and D. Pescia*
- Effect of Au Underlayer on Perpendicular Magnetic Anisotropy in Au/Co/Au(111) Sandwiched Films — *A. Murayama, K. Hyomi, J. Eickmann, and C. M. Falco*
- Interface Orbital Moment Anisotropy in CoPd Multilayers — *H. A. Dürr, G. Van Der Laan, J. Vogel, M. Finazzi, and J. B. Goedkoop*
- Magnetic Anisotropy and its Microstructural Origin in Epitaxially Grown SmCo Thin Films — *M. Benaissa, K. M. Krishnan, E. E. Fullerton, and J. S. Jiang*
- Magnetoelectric Néel Anisotropies — *R. Skomski*
- Spin-Reorientation Transitions in Ultrathin Ferromagnetic Films Under Applied Field — *Y. T. Millev, H. P. Oepen, and J. Kirschner*
- Symmetry-Induced Magnetic Anisotropy in Ultrathin Planar Striped Co Films with and without Cu Decoration — *L. Zhong, X. Wang, and A. J. Freeman*
- Changes of Morphology, Structure, and Magnetism of Fe on Stepped Cu(111) — *M. Klaua, J. Shen, P. Ohresser, H. Jenniches, J. Barthel, C. V. Mohan, and J. Kirschner*
- The Effect of Interfacial Steps on the Ferromagnetic/Antiferromagnetic Interface of Thin Fe Films on Cr(001) — *E. J. Escorcia-Aparicio, H. J. Choi, W. L. Ling, R. K. Kawakami, and Z. Q. Qiu*
- Magnetic Easy Axis Engineering in Ultrathin Cu/Co/Cu(110) Structures — *B.-C. Choi, S. Hope, E. Gu, and J. A. C. Bland*
- First Principles Calculations of Interlayer Exchange Coupling in bcc Fe/Cu/Fe Structures — *M. Kowalewski, B. Heinrich, T. C. Schulthess, and W. H. Butler*
- On Rotational Eddy Current Losses in Steel Laminations — *I. D. Mayergoyz*
- Dynamic Preisach Modelling of Ferromagnetic Laminations Under Distorted Flux Excitations — *L. R. Dupré, O. Bottauscio, M. Chiampi, F. Fiorillo, M. L. Bue, J. Melkebeek, M. Repetto, and M. Von Rauch*
- Eddy Current Analysis for the Pipe Welding — *H. Tsuboi, K. Ikeda, M. Kurata, K. Kainuma, and K. Nakamura*
- Analysis of Eddy-Current Brake for High-Speed Railway — *P. J. Wang and S. J. Chiueh*
- Loss Separation Analysis in Ferromagnetic Sheets Under PWM Inverter Supply — *A. Boglietti, M. Chiampi, M. Repetto, O. Bottauscio, and D. Chiarabaglio*
- Current Flow in Long Conductors with a Step Conductivity Change — *K. V. Namjoshi, J. D. Lavers, and P. P. Biringer*

- A Model for Impedance of Planar RF Inductors Based on Magnetic Films — *A. Gromov, V. Korenivski, K. V. Rao, R. B. van Dover, and P. M. Mankiewich*
- Numerical Study of Electric Diffusion Effect Due to Imperfect Electrical Contacts — *B.-K. Kim and K.-T. Hsieh*
- Crack Size and Shape Determination by Moving Magnetic Field Type Sensor — *M. Enokizono, Y. Tsuchida, and T. Chady*
- Ohmic Losses Calculation in SMPS Transformers: Numerical Study of Dowell's Approach Accuracy — *F. Robert, P. Mathys, and J.-P. Schauwers*
- Analysis of Isotropic Materials with Vector Hysteresis — *O. Bottauscio, D. Chiarabaglio, C. Ragusa, M. Chiampi, and M. Repetto*
- Eddy Current Hysteresis and the Preisach Model — *I. D. Mayergoyz*
- Simulation of Field-Temperature Effects in Magnetic Media using Anisotropic Preisach Models — *A. A. Adly and I. D. Mayergoyz*
- Eddy Current and Hysteresis Losses in Ferromagnetic Media — *V. Maló Machado and A. Lopes Ribeiro*
- Hysteretic Energy Losses in Media Described by Vector Preisach Model — *G. Friedman and I. D. Mayergoyz*
- On the Role of the Statistics in the Applicability of the Preisach Transformation — *K. Metlov, I. Tomáš, G. Vértessy, and M. Pardavi-Horváth*
- A Preisach Model for Aftereffect — *E. Della Torre and L. H. Bennett*
- Identification of the Preisach Parameters of a Three Quadrant Medium — *J. Lou, L. H. Bennett, and E. Della Torre*
- Interaction Effects in CrO₂ Audio Tape: AC Versus Thermal Demagnetization — *P. D. Mitchler, R. M. Roshko, and E. D. Dahlberg*
- A New Algorithm for Thermal Decay Simulations — *I. Klik and Y. D. Yao*
- 1/f Nyquist Magnetic Noise, Magnetic Viscosity and Hysteresis — *A. Maraner, S. Vitale, and G. Bertotti*
- Modeling of Magnetic Properties of Heat Treated Dy-Doped NdFeB Particles Bonded in Isotropic and Anisotropic Arrangements — *X. Fang, Y. Shi, and D. C. Jiles*
- Modeling of Hysteresis Loops of Ferrite Cores Excited by a Transient Magnetic Field — *N. L. Mi, R. Oruganti, and S. X. Chen*

MAGNETIC SENSORS AND COMPONENTS

- Increased Field Sensitivity in Co/Cu Multilayers with Soft Adjacent Layers — *D. B. Jardine, N. D. Mathur, M. G. Blamire, and J. E. Evetts*
- InAs/(Al,Ga)Sb Quantum Well Structures for Magnetic Sensors — *M. Behet, J. Das, J. De Boeck, and G. Borghs*
- Fluxgate: Tuned vs. Untuned Output — *P. Ripka and S. W. Billingsley*
- Pyro Photosensor Utilizing Thermally-Sensitive Magnetic Thin Film — *T. Yoshida, Y. Ajishi, H. Osada, S. Chiba, N. Tayama, K. Seki, and H. Matsuki*
- Development of a Moving Magnetic Flux Type Sensor using Shading Coils for ECT — *Y. Tsuchida, T. Chady, and M. Enokizono*
- Effect of Stress on the Bamboo Domains and Magnetization Process of CoSiB Amorphous Wire — *J. N. Nderu, M. Takajo, J. Yamasaki, and F. B. Humphrey*
- A Remotely Interrogatable Sensor for Chemical Monitoring — *P. G. Stoyanov, S. A. Doherty, C. A. Grimes, and W. R. Seitz*
- Dependence of Large Barkhausen Jump on Length of a Vicalloy Fine Wire with Torsion Stress — *S. Abe, A. Matsushita, and M. Naoe*
- High Frequency Carrier Type Bridge-Connected Magnetic Field Sensor — *M. Takezawa, H. Kikuchi, K. Suezawa, M. Yamaguchi, K. Ishiyama, and K. I. Arai*
- Preparation and Properties of Elastically Coupled Electro-Magnetic Elements with a Bonding Structure — *K. H. Shin, M. Inoue, and K. I. Arai*
- Geometry Effects on Low Frequency Noise in Giant Magnetoresistance (GMR) Sensors — *A. F. Md. Nor, E. W. Hill, and M. R. Parker*
- Thermal Activation of Spin Wave Modes in Co Based Multilayers — *M. A. Wongsam and R. W. Chantrell*
- A New Bi-Directional Inductive Force Sensor — *V. Lemaquand*
- Hard-Soft GMR Sensors with Co-Rh based Artificial Antiferromagnetic Subsystem — *H. A. M. van den Berg, G. Rupp, W. Clemens, G. Gieres, M. Vieth, J. Wecker, and S. Zoll*
- A New Giant Magneto-Impedance Head using Magnetic Microstrip Lines — *N. Jiang, K. Yamakawa, N. Honda, and K. Ouchi*
- New Multi-Chambered Power Magnetics Concepts — *G. E. Bloom*
- Application and Analysis of Adjustable Profile High Frequency Switchmode Transformer Having a U-Shaped Winding Structure — *J. Lu, F. P. Dawson, and S. Yamada*
- Analysis of Frequency Characteristics of Small-Sized Wide-Band Compound Transformers — *N. Nishizuka, M. Sato, and Y. Li*

- Design and Analysis of Noise-Reduction Transformer Based on Equivalent Circuit — *T. Yanada, S. Minowa, O. Ichinokura, and S. Kikuchi*
- An Analytical Method of a Planar Parametric Transformer Based on the Magnetic Circuit Model — *Y. Sakamoto, M. Ohta, M. Natsusaka, and K. Murakami*
- Design and Simulation of Film Transformer on Flexible Polyamide Film in Very High Frequency Range — *H. Tsujimoto*
- 2D and 3D Simulation of Toroidal Type Thin Film Inductors — *H. J. Ryu, S. D. Kim, J. Kim, J. J. Lee, J. Kim, S. H. Han, H. J. Kim, and C. H. Ahn*
- The Characteristics of Low Temperature Co-Fired Multilayer Chip LC Filters — *H. M. Sung, C.-J. Chen, L.-J. Wang, and W.-S. Ko*
- Packaging-Compatible Microinductors and Microtransformers with Screen-Printed Ferrite using Low Temperature Processes — *J. Y. Park and M. G. Allen*
- A Microfabricated Transformer for High-Frequency Power or Signal Conversion — *M. Xu, T. M. Liakopoulos, C. H. Ahn, S. H. Han, and H. J. Kim*
- The Effect of Magnetic Film Structure on the Inductance of a Planar Inductor — *T. Inoue, K. Nishijima, S. Yatabe, T. Mizoguchi, and T. Sato*
- Design of High Frequency Inductors Based on Magnetic Films — *V. Korenivski and R. B. van Dover*
- Inductive Microtransformer Exploiting the Magnetoelastic Effect — *L. H. Rissing, S. A. Zielke, and H. H. Gatzert*

MICROWAVE MAGNETICS

- Mode Beating of Spin Wave Beams in Ferrimagnetic $\text{Lu}_{2.04}\text{Bi}_{0.96}\text{Fe}_5\text{O}_{12}$ Films — *O. Büttner, M. Bauer, C. Mathieu, S. O. Demokritov, B. Hillebrands, P. A. Kolodin, M. P. Kostylev, S. Sure, H. Dötsch, V. Grimalsky, Y. Rapoport, and A. N. Slavin*
- Ferromagnetic Resonance Damping in Garnets: Comparison Between Saturated and Unsaturated States — *T. Taffary, D. Autissier, F. Boust, and H. Pascard*
- Enhanced Microwave Magnetic Properties in Nonstoichiometric Yttrium Iron Garnets for High Power Applications — *Y. S. Cho, V. L. Burdick, and V. R. W. Amarakoon*
- Shape-Optimized Ferromagnetic Particles with Maximum Theoretical Microwave Susceptibility — *R. M. Walser, W. Win, and P. M. Valanju*
- Parametric Frequency Conversion with Amplification of a Weak Spin Wave in a Ferrite Film — *B. A. Kalinikos, N. G. Kovshikov, M. P. Kostylev, and H. Benner*
- Theory of MSFVW Excitation in a YIG Film by a Finite-Length Microstrip Transducer — *L. P. Peng, J. P. Parekh, and H. S. Tuan*
- Experimental Investigation of the Nonlinear Interaction Between Optical Guided Waves and Magnetostatic Forward Volume Waves in a Bi-YIG Film — *J. Kurumida and N. S. Chang*
- Design Procedure for Ferrite Microstrip DC Blocks — *M. R. M. L. Albuquerque and A. G. d'Assunção*
- Axially Polarized Wiggler Radiation from a Toroidal Electron Beam Source — *H. A. Leupold, A. S. Tilak, and M. M. Visosky*
- Technical Characteristics of a Novel Helical-Groove Traveling-Wave Tube Structure — *T. M. Walleit, K. R. Vaden, J. Freeman, and A. Haq Qureshi*

MAGNETIC RECORDING HEADS

- Anisotropy Control in Fabrication Process for NiMn Spin-Valve Dual Element Heads — *T. Ishi, T. Suzuki, N. Ishiwata, M. Nakada, K. Yamada, K. Shimabayashi, and H. Urai*
- Effect of Seed Layer on the Magnetoresistance Characteristics in a-CoNbZr-Based Spin Valves — *H. S. Cho, F. Ueda, C. Hou, and H. Fujiwara*
- Thermal Stability of CoFe, Co and NiFe/Co Spin Valves — *A. M. Zeltser, K. Péntek, and M. Menyhárd, and A. Sulyok*
- Activation Energy of Interdiffusion and Interface Structure for CoFe/Cu Spin-Valves — *A. T. Saito, H. Iwasaki, Y. Kamiguchi, H. N. Fuke, and M. Sahashi*
- Enhancement of Magnetoresistance Characteristics in Spin Valve Structures by Two-Step Sputter Deposition — *C.-M. Park and K. H. Shin*
- The Distribution of Blocking Temperature in NiFe-Ru_xRh_yMn Bilayers — *S. Araki, M. Sano, M. Ohta, Y. Tsuchiya, K. Noguchi, H. Morita, and M. Matsuzaki*
- Thermal and Magnetic Stability of Unidirectional Anisotropy in Spin-Valve Magnetoresistive Heads — *N. Ohshima, M. Nakada, and Y. Tsukamoto*
- New Soft Magnetic CoNiFe Plated Films with High $B_s = 2.0\text{--}2.1\text{ T}$ — *T. Osaka, M. Takai, K. Hayashi, Y. Sogawa, K. Ohashi, Y. Yasue, M. Saito, and K. Yamada*
- Improved Magnetic Anisotropy and Magnetostriction by Laminating FeAl(N) with Permalloy to Multilayers — *W. Maass and H. Rohrmann*
- High Frequency Initial Permeability of NiFe and FeAlN — *W. P. Jayasekara, J. A. Bain, and M. H. Kryder*

- Magnetostriction Constants of (110) Oriented Epitaxially Grown FeTaN Thin Films — *L. Varga, H. Jiang, T. J. Klemmer, and W. D. Doyle*
- Texture and Magnetic Properties of FeTaN Films Bias-Sputtered on Sloping Surfaces — *J. Hong, S. X. Wang, and K. Rook*
- Control of Asymmetry of Spin-valve Heads Based on Micromagnetic Analysis — *K.-I. Yamada, H. Kanai, Y. Uehara, and J. Toda*
- A Study of Voltage Fluctuation, Noise and Magnetic Instability in Spin Valve GMR Recording Heads — *A. Wallash*
- Magnetic Domain Instability in MR Heads Due to Overlaid Structure of Permanent Magnet Film — *C. Mitsumata, K. Kikuchi, and T. Kobayashi*
- Crossfeed Response of DMR vs. SAL Multi-Track Heads — *F. Z. Wang, L. N. He, D. J. Mapps, D. T. Wilton, W. W. Clegg, and P. Robinson*
- Multitrack Thin Film Heads for the Digimax™ Tape Storage System — *J. J. M. Ruigrok, H. W. van Kesteren, S. R. Cumpson, D. J. Adelerhof, S. B. Luitjens, E. A. Draaisma, and A. Hoogendoorn*
- Newly Developed Inductive Write Head with Electroplated CoNiFe Film — *K. Ohashi, Y. Yasue, M. Saito, K. Yamada, T. Osaka, M. Takai, and K. Hayashi*
- Two Dimensional Model of Eddy Currents and Saturation in Thin Film Write Heads — *A. F. Torabi, M. L. Mallary, R. Perry, and G. Kimball*
- Off-track Performance of Thin Film Single Pole Head for Perpendicular Double-Layered Media — *H. Yamada, H. Muraoka, Y. Sugita, and Y. Nakamura*
- A New Write Head Trimmed at Wafer Level by Focused Ion Beam — *T. Koshikawa, A. Nagai, Y. Yokoyama, T. Hoshino, and Y. Ishizuki*
- Extremely Low Inductance Thin-Film Single-Pole Head on Flying Slider — *H. Muraoka, K. Sato, Y. Nakamura, T. Katakura, and K. Yazawa*
- Active Cancellation of Mutual Inductance in Split-Coil Thin-Film Heads — *S. E. Stupp and G. R. Lovelace*
- Writer Performance Improvement in MR Head with Over-Sized Trailing Poles Technique — *E. Leung, M. Hayashi, R. Leung, K. Ino, N. Matono, S. Takahashi, and M. Fujita*
- GMR-DMR Read-Element Characterization and Projections of Head Performance on High Areal Density Rigid Media — *I. G. Trindade, M. H. Kryder, P. P. Freitas, and N. Smith*
- Two Leg, Side by Side, 0.6 to 1.0 Micron Wide, High Output, Vertical, GMR, Head Sensors — *A. V. Pohm, J. M. Anderson, R. S. Beech, and J. M. Daughton*
- Three-Dimensional Analysis of Dual Track Complementary Type of Heads for Perpendicular Magnetic Recording — *T. Ichihara, S. Nakagawa, H. Matsumiya, and M. Naoe*
- High-Density Recording using MR Heads in Helical-Scan Tape Systems — *T. Ozue, T. Shirai, T. Saito, T. Ikegami, H. Kano, and S. Onodera*
- Fabrication and Characterization of Contiguous Permanent Magnet Junctions — *M. Xiao, A. J. Devasahayam, and M. H. Kryder*
- Spin-Valves with Bias Compensation Layer — *H. Kanai, K. Yamada, M. Kanamine, and J. Toda*
- A Self-Biased Spin Valve Sensor with a Longitudinally Pinned Layer — *T. Suzuki and H. Matsutera*
- Characteristics of NiFe/CuNi Multilayer GMR Sensors For Vertical GMR Heads — *T. Mizuguchi, S. Terada, T. Miyauchi, and A. Matsuzono*
- Planar, Contact, Yoke GMR Head vs. Conventional, Flying, Shielded GMR Head: A Comparative Study — *Y. Yoshida, K. Araki, S. Sugano, and Y. Kaneta*
- Micromagnetic Analysis and Current Biasing of Dual-Stripe GMR and Dual-GMR Sensors for High Density Recording — *P. P. Freitas, S. Cardoso, and N. J. Oliveira*
- A New Method of Calculating the Medium Field and the Demagnetizing Field for MR Heads — *Y. Suzuki and C. Ishikawa*
- Read Sensitivity in Abutted-Junction Type Spin-Valve Head — *K.-I. Takano, N. Yamanaka, and M. Matsuzaki*
- Magnetic Changes in GMR Heads Caused by Electrostatic Discharge — *A. Wallash and Y. K. Kim*
- ESD Induced Pinned Layer Reversal in Spin-Valve GMR Heads — *M. Takahashi, T. Maeda, K. Inage, M. Sakai, H. Morita, and M. Matsuzaki*
- Amplitude and Asymmetry Correlation Study Between Quasi-Static and Dynamic Electrical Testing of MR Sensors — *J. Zhu and M. Loera*

MAGNETIC RECORDING MEDIA

- Thermal Aftereffects in Thin Film Magnetic Recording Media — *Y. Hosoe, T. Kanbe, K. Tanahashi, I. Tamai, S. Matsunuma, and Y. Takahashi*
- Thermal Stability and Nanostructure of CoCrPt Longitudinal Recording Media — *M. Yu, M. F. Doerner, and D. J. Sellmyer*
- Effects of Thin Cr Interlayer on Time Decay of Magnetization and Magnetization Reversal for CoCrTaPt Thin Film Media — *J.-P. Wang, L.-P. Tan, T. F. Liew, E. Teng and P.-W. Wang*

- Dynamic Coercivity Effects in Thin Film Media — *H. J. Richter, S. Z. Wu, and R. Malmhäll*
- Numerical Simulations of the Effect of Record Field Pulse Length On Medium Coercivity at Finite Temperatures —
H. N. Bertram and Q. Peng
- Coercivity and Frequency Dependence of Track Widths and Erase Bands in Thin Film Media — *L. Mei, M. E. Schabes, and N. H. Yeh*
- Quantitative MFM Study of the Global and Local Magnetic Roughness of the DC-Demagnetized State of Thin Film Media — *X. Song, Q. Chen, C. Leu, and R. Ranjan*
- Under-Keeped Media with MR Heads — *M. Nichols, B. M. Lairson, T. M. Coughlin, B. Gooch, J. Kehl, and J. Perez*
- Recording Physics of Keeped Inductive Media — *E. T. Yen, H. J. Richter, G.-L. Chen, G. Rauch, and T. M. Coughlin*
- Temperature Dependence of Magnetocrystalline Anisotropy Energy Determined using Co-Cr-Ta Single Crystal Thin Films — *N. Inaba, M. Futamoto, and A. Nakamura*
- CrMn Underlayers for CoCrPt Thin Film Media — *L.-L. Lee, D. E. Laughlin, and D. N. Lambeth*
- Chromium Segregation in CoCrTa/Cr and CoCrPt/Cr Thin Films for Longitudinal Recording Media — *J. E. Wittig, T. P. Nolan, C. A. Ross, M. E. Schabes, K. Tang, R. Sinclair, and J. Bentley*
- The Effect of Carbon Overcoat Diffusion on CoCrTa/Cr Thin-Film Media — *J. J.-K. Chang, K. E. Johnson, H. Kawayoshi, P. Ling, and M. Strathman*
- Cr-Ta₂O₅ Seedlayer for Recording Media on Alternative Substrates — *W. Xiong and H.-L. Hoo*
- The Dependence of Media Noise on the Magnetic Cluster Size for Co Based Thin Film Media Fabricated under Ultra Clean Sputtering Process — *M. Takahashi, A. Kikuchi, H. Hara, and H. Shoji*
- Effects of Ultra-High Vacuum on Crystallographic, Recording and Magnetic Properties of Thin Film Media —
C. Gao, S. Wu, J.-P. Chen, R. Malmhall, C. Habermeier, R. Sinclair, H. Laidler, and K. O'Grady
- The Effect of fcc Grains on the Magnetic and Recording Properties of Thin Film Media — *K. O'Grady, N. S. Walmsley, C. F. Wood, and R. W. Chantrell*
- CoCrTa Intermediate Layers on NiAl Underlayers for CoCrPt Longitudinal Thin Film Magnetic Media — *J. Zhou, D. E. Laughlin, and D. N. Lambeth*
- Orientation Ratio Reduction Through Pre-Deposition Substrate Annealing — *B. Y. Wong, J. Ying, and H. Tran*
- Recording Performance of Thin Film Media with Various Crystallographic Preferred Orientations on Glass Substrates —
M. Mirzamaani, X. Bian, M. F. Doerner, J. Li, and M. Parker
- Magnetic and R/W Properties of CoPt-SiO₂ Granular Media — *I. Kaitsu, A. Inomata, I. Okamoto, and M. Shinohara* ...
- Fabrication, Micromagnetic and Recording Properties of CoCrPt on Plastic Disks — *B. R. Acharya, E. N. Abarra, G. N. Phillips, T. Suzuki, K. Adachi, N. Kitagaki and M. Aihara*
- Magnetic Interaction in Co-Cr-Pt-Ta-Nb Media: Utilization of Micromagnetic Simulation — *H. Akimoto, I. Okamoto, and M. Shinohara*
- Small $-dH_c/dT$ Characteristics of CoPt Granular and Thin Film Recording Media — *A. Kikitsu, K. Yusu, K. Ichihara, and T. Tanaka*
- High-Density Recording Capability of Granular Media Composed of Co-Pt Grains and SiO₂ Matrix — *K. Ichihara, A. Kikitsu, K. Yusu, F. Nakamura, and H. Ogiwara*
- Time Decay of the Remanent Magnetization in Longitudinal Thin Film Recording Media as a Function of Distributions of Grain-Size and Easy-Axis Orientation — *C. Yang, J. M. Sivertsen, and J. H. Judy*
- Micromagnetic Study of Network Media — *J.-G. Zhu and H. Fang*
- Thermal Stability of Ultra-Thin Co Recording Media — *H. Gong, W. Yang, D. N. Lambeth, M. Rao, and D. E. Laughlin*
- Effects of ECR Ion Shower Treatment on the Magnetic and Recording Properties of CoCrTaPt Thin Film Media —
Y. Okumura, M. Yasui, T. Akita, M. Maeda, and X. B. Yang
- Effect of Grain Size Dispersion on Read/Write Properties in Thin Film Recording Media Affected by Thermal Fluctuation — *Y. Nakatani, N. Hayashi, Y. Uesaka, and H. Fukushima*
- DC Erasure and Demagnetizing Fields on Written Bits in High Density Longitudinal Media — *E. N. Abarra, G. N. Phillips, I. Okamoto, and T. Suzuki*
- Comparison of Time-Decay of Read-Back Signals in Keeped and Non-Keeped Media — *J. Chen, J. H. Judy, and T. Coughlin*
- Effects of Pt addition on the magnetic and microstructural properties of CoC granular films — *J.-J. Delaunay, T. Hayashi, M. Tomita, and S. Hirono*
- Read Write Characteristics of Hexagonal Barium Ferrite Sputtered Films Prepared by Post Deposition Annealing —
A. Morisako, M. Matsumoto, and M. Naoe
- Microscopic Magnetization Structures and Noise in Single-Layer Perpendicular Thin Film Media — *Y. Honda, Y. Hirayama, K. Ito, and M. Futamoto*
- Effect of Medium Thickness on the Signal-to-Noise Ratio of Perpendicular Media — *Y. Ikeda, Y. Sonobe, and H. Uchida*

- Preparation and Characteristics of Co-Zn Ferrite Rigid Disks without Protective Layers for High Density Recording — *N. Matsushita, M. Ichinose, S. Nakagawa, and M. Naoe*
- Nano-size Magnetic Crystallite Formation in Co-Cr Thin Films For Perpendicular Recording Media — *S. Kadokura, M. Naoe, S. Nakagawa, and Y. Maeda*
- Thermal Relaxation in Perpendicular Double-Layered Media — *W. H. Jiang, H. Muraoka, Y. Sugita, and Y. Nakamura*
- Barium Ferrite Thin Films Without a Dead-Layer — *Y. Chen, M. Rao, D. E. Laughlin, and M. H. Kryder*
- Low Noise Co-Cr-Nb Perpendicular Recording Media with High Squareness — *N. Honda, J. Ariake, K. Ouchi, and S.-I. Iwasaki*
- Barium Ferrite Films Grown by Laser Ablation — *A. Lisfi, J. C. Lodder, P. de Haan, M. A. Smithers, and F. J. G. Roesthuis*
- MFM Observation of Localized Demagnetization in Magnetic Recordings — *A. Jander, P. Dhagat, R. S. Indeck, and M. W. Muller*
- A Comparison between Different Methods for Evaluating the Particle Interactions in Magnetic Recording Systems — *G. Bottoni, D. Candolfo, and A. Cecchetti*
- Analytical Determination of the LLG Zero-Damping Critical Switching Field — *D. G. Porter*
- Development of an Advanced Metal Particulate Tape — *H. Inaba, K. Ejiri, K. Masaki, and T. Kitahara*
- Influence of Magnetic Interaction and Particle Length on MP Tape Noise — *N. Nagai and M. Inoue*
- Measurement of Vector Minor Loops — *F. Vajda and E. D. Torre*
- Epitaxial Growth of NiZn Ferrite on Barium Ferrite Particles — *H.-S. Jung and Y.-K. Hong*
- Non-Arrhenius Behavior in Single Domain Particles — *E. D. Boerner and H. N. Bertram*
- The Effect of Particle Size on the Thermal Switching Characteristics of Metal Particle Tapes — *S. M. Stinnett and W. D. Doyle*
- Mechanical Orientation of Advanced Metal Particle Dispersions — *L. S. Prichard, K. O'Grady, and P. I. Mayo*
- Self-Assembly in Model Magnetic Inks — *P. B. Visscher and Y. Günel*

HEADS AND MEDIA INTERFACES IN MAGNETIC RECORDING

- A New Sub-Femto Slider for Mass Production Planar Silicon Heads — *J.-P. Lazzari, C. Pisella, and L. Tosi*
- Take Off Measurement of Pico Sliders on Laser Zone Textured Media — *D. Harris, S. Venkatesan and K. O'Brien*

Magnetic Microscopy and Imaging I

R. D. Gomez, Chairman

Time-resolved scanning Kerr microscopy of ferromagnetic structures (invited)

M. R. Freeman, W. K. Hiebert, and A. Stankiewicz

Department of Physics, University of Alberta, Edmonton T6G 2J1, Canada

Time-resolved microscopy enables valuable new measurements of the dynamics of resonance and relaxation in a range of magnetic systems. An overview of the scope of applications to ferromagnetic microstructures is presented. These include observations of ferromagnetic resonance and spatially nonuniform modes of oscillation, studies of magnetization reversal, and characterizations of the speed of magnetic recording devices. © 1998 American Institute of Physics. [S0021-8979(98)36511-1]

I. INTRODUCTION

Recently, novel experimental information concerning the dynamics of a variety of magnetic systems has been obtained using picosecond time-resolved laser techniques combined with diffraction-limited optical microscopy. Ultrafast optical methods have been in use for some time in the extraction of relaxation and resonance information from magnetic systems.¹⁻⁴ The addition of microscopic spatial resolution powerfully extends the approach to much smaller specimens, enabling measurements of relaxation in micrometer-scale structures, as well as some imaging of spatially nonuniform dynamics.^{5,6} In this paper we describe the study of ferromagnetic dynamics in small permalloy structures using this technique. A similar procedure applies to the time-domain characterization of devices such as high-speed magnetic recording heads.

In addition to the good spatial and temporal resolution achieved using an optical technique, another key aspect is the ability to perform vector measurements of the magnetization. The component of magnetization parallel to the wave vector of the incident light is resolved in the experiments. A vector measurement is not crucial to paramagnetic relaxation measurements, but is essential in order to perform magnetic resonance and ferromagnetic relaxation studies. Controlling the optical configuration, we are able to track dynamical excursions of the magnetization in three dimensions through polar and longitudinal Kerr effect measurements.

II. EXPERIMENTAL DETAILS

An example of an experimental geometry for spatially resolved time-domain ferromagnetic resonance measurements is shown in Fig. 1.⁶ The single turn lithographic coil is patterned from a gold film with a titanium adhesion layer. A fast electrical pulse generated using a photoconductive switch propagates around the coil, inducing a transient magnetic field at the sample, perpendicular to the substrate (the tipping pulse). The rise time of this pulse at the sample is limited to ~ 20 ps by dispersion of the coil leads, and the

decay time constant is ~ 500 ps. Peak tipping field amplitudes are limited to ~ 30 Oe with this coil. The static magnetic field is applied in the plane of the sample, and the polar Kerr effect is used to record the out-of-plane component of the magnetization. Resonant precession of the magnetization (about the static field) induced by the tipping pulse is reflected in oscillations of the polar Kerr signal.

The permalloy films used in this work are sputter deposited in a load-locked ultrahigh vacuum chamber pumped to a base pressure of $\sim 5 \times 10^{-8}$ Torr. A permanent magnet assembly is used to apply an *in situ* static field of approximately 150 Oe in the plane of the substrate to establish an easy axis. The resulting films have low coercivity (< 2 Oe in the easy direction), and low resistivity ($\sim 20 \mu\Omega$ cm) indicating very little oxidation. SIMS analysis of the films show the composition to be 83% Ni 17% Fe (by weight), fairly close to the 81/19 proportion of the target. Patterning of the films is accomplished through photolithography and wet chemical etching, yielding the very smooth edges with a slight undercut profile as seen in Fig. 1(b).

FIG. 1. Electron micrographs of the $8 \mu\text{m}$ diameter permalloy disk sample. Left panel: plan view, showing the surrounding lithographic gold coil. Right panel: tilted close-up view, clearly showing the clean edge of the disk.

FIG. 2. Examples of the response to the pulsed field of the out-of-plane component of magnetization, measured at the center of the disk by the polar Kerr effect. The solid lines are fits to the data using the Landau-Lifshitz-Gilbert equation, using the same parameters for each value of the static field.

III. RESULTS

A. Resonance

The modal resonance frequencies are determined by the maxima in the power spectra of Fourier transformed time-domain data. The in-plane magnetic field dependence of the characteristic frequency is well described by the Kittel relation for an infinite plane, as may be expected for such a large (on the scale of the domain wall width) disk. Modeling the time-domain data in more detail through numerical integration of the Landau-Lifshitz-Gilbert equation, we find very good agreement.⁶ Data are shown in Fig. 2 for a range of values of the in-plane field. The measurements (shown by the dotted lines in the figure) were made with the $0.7\ \mu\text{m}$ laser spot focused at the center of the particle. The $t=0$ position is arbitrary, corresponding to the initial position of the delay line at a location yielding a reasonable baseline determination before onset of the signal. Using a pulse shape determined from higher field data by the procedure established in Ref. 7, the curves are all fit using the same set of

FIG. 3. A collection of full spatial images of the polar Kerr signal at times corresponding to the successive peaks in the signal at the center of the disk in a static field of 500 Oe.

parameters. The results of the fit are shown by the solid lines. Only the dimensionless Gilbert damping parameter is adjustable, and we find $\alpha=0.008$, in reasonable agreement with earlier careful microwave measurements of Patton and co-workers.⁸ Note that these results represent the response of the magnetization to a very broad-band excitation. The high frequency components associated with the rising edge of the pulse excite the resonant oscillations, which then ring-down according to their intrinsic damping rate. Meanwhile the magnetization vector parametrically follows the slowly decaying tail of the field pulse (consisting of that part of the spectrum of the broad-band excitation below the resonance frequency), giving rise to the offset of the centerline through the envelope of the oscillations.

Time-resolved images of the magnetization across the whole disk clearly show the presence of nonuniform modes of oscillation, however. At these dimensions we are in an intermediate size regime, where the modal frequencies are not yet strongly influenced by size effects but the spatial response definitely is.⁶ Figure 3 shows a set of time-resolved magnetic images of the particle. With the static bias field at 500 Oe (horizontal), an image was taken for a series of time delays corresponding to successive peaks in the oscillations measured at the disk's center. Strikingly apparent are the enhanced initial responses at the edges (dark corresponds to

higher signal), that subsequently seem to propagate toward the center as a kind of shock wave. The effective velocity is on the order of 10^4 m/s, much faster than a domain wall velocity, for example. The observation of enhanced response at the edges along the field direction is qualitatively consistent with the fact that in static equilibrium these edges are already demagnetized, and should be able to respond to the tipping field more easily. In contrast, no such effects are seen at the edges one-quarter of a rotation around the disk from these points, where there are no free poles in the initial magnetic configuration. In these data, a reflection in the electrical pulse induces a bit of additional structure after the fifth peak. At long time delays, the spatial mode of oscillation becomes more uniform again. To highlight the nonuniformity, the gray scale in each image is adjusted to span between the minimum and maximum levels of the signal. In the later frames (8,9,10) the signal becomes quite uniform across the disk, with variations not much greater than the noise level in the measurement. The scaling procedure then mainly highlights the noise, which appears as graininess.

From these images we can conclude that we should in fact expect discrepancies between the Landau-Lifshitz-Gilbert model and the time domain data for this sample. Consistently poorer agreement is found between the data and the model in Fig. 2 over a time interval that begins coincident with the arrival of the nonuniform response at the center of the structure. A more detailed numerical model taking into account the initial magnetic configuration of the disk seems essential to further quantitative progress.

B. Reversal

In-plane dynamics of the magnetization, and most specifically those aspects related to magnetization reversal, are also of great interest at the present time.⁹⁻¹³ In order to address these questions using time-resolved microscopy, it is only necessary to reconfigure the "vector geometry." We measure the in-plane components of the magnetization (parallel and perpendicular to the static magnetic field) using the longitudinal Kerr effect implemented in the traditional manner by masking half of the beam. While this is the simplest approach, one must beware that a mix of polar and longitudinal signals is observed when there is also an out-of-plane magnetization present. In addition the effective numerical aperture in the masking direction is halved, resulting in an elongated focus and some loss of spatial resolution.

The other important geometric change is to place the transient magnetic field in the plane of the sample. Placing the sample directly on top of a current carrying transmission line straightforwardly does this. A cross-sectional schematic of the arrangement used in this work is illustrated in Fig. 4. The transmission line is 300 nm by 40 μ m gold, relatively thick for high current carrying capacity, and broad for magnetic field uniformity at the sample. The current pulses in this case are generated by an avalanche transistor pulser (Picosecond Pulse Labs Model 2000D). An insulating spacer (25 nm SiO_2) on top of the gold electrically insulates the permalloy from the transmission line, and optimally positions the magnetic sample in the in-plane field. The calcu-

FIG. 4. (a) Cross-sectional geometry showing the configuration for applying transient fields in the plane of the sample. (b) Calculated cross-sectional transient field profile for the volume occupied by the samples.

lated field distribution above the transmission line is shown in Fig. 4(b).

The permalloy samples for this study are rectangular bars, again produced by sputtering in the UHV system followed by optical lithography and wet chemical etching. Initial magnetic characterizations are performed optically, using a small electromagnet to apply in-plane field to the sample. Spot measurements of the hysteresis are performed, with the laser focused at specific locations. As these results are strongly position dependent (the bars are much easier to saturate near the center than near the ends) we also use an imaging method to characterize the static magnetic properties of the samples. The synchronous response to low frequency (280 Hz) ac fields is measured, yielding a signal representing the difference of the magnetization between positive and negative fields. Magnetic images taken for different field amplitudes show how the hysteresis varies as a function of position. A typical result is shown in Fig. 5. This is the longi-

FIG. 5. A longitudinal Kerr image showing the signal change due to magnetization reversal of the 10×4 μ m bar in a ± 30 Oe field switching at 280 Hz.

FIG. 6. Changes of the x component of magnetization (larger signals shown brighter) for a $20 \times 6 \mu\text{m}$ bar in a -5 Oe static biasing field. (a) Shift of the domain wall after 5.5 ns in a small tipping field. (b) and (c) are typical y - t diagrams for small and large tipping fields, respectively, where a linear vertical spatial scan across the center of the bar is repeated for increasing delay times. Note the change in time scale between (b) and (c).

tudinal Kerr signal (x component of the magnetization, parallel to the static field) from a $4 \times 10 \mu\text{m}$ particle for a ± 30 Oe square-wave field modulation, showing a uniformly magnetized and saturated central region. Recording the different Kerr components reveals information about the magnetic anisotropy at the ends (due mainly to demagnetizing effects). Such static images provide a direct point of comparison for the dynamical studies. A very detailed portrait of static reversal in permalloy bars was developed much earlier through Bitter pattern images, which have higher spatial resolution than the present optical experiments.¹⁴

A first glimpse at the dynamical information accessible in time-resolved studies of magnetization reversal is seen in the following data of the response of a nonuniformly magnetized permalloy rectangle to a pulsed field in the plane of the particle. We examine a $20 \mu\text{m} \times 6 \mu\text{m}$ rectangle (50 nm thick) with the static bias magnetic field parallel to the long direction. This bar is oriented transverse to the current flow direction of the transmission line so that the transient magnetic field is parallel (or antiparallel) to the bias field. In a field of -5 Oe, the static configuration of the particle corresponds to two antialigned domains along most of the length of the bar, with the domain wall near the center, and some closure domains at the ends. Time-resolved measurements are then performed to study the approach to saturation induced by the (0.4 ns rise time, 1.5 ns fall time, 10 ns duration, opposite polarity to the static field) pulsed magnetic fields, starting from this simple demagnetized state.

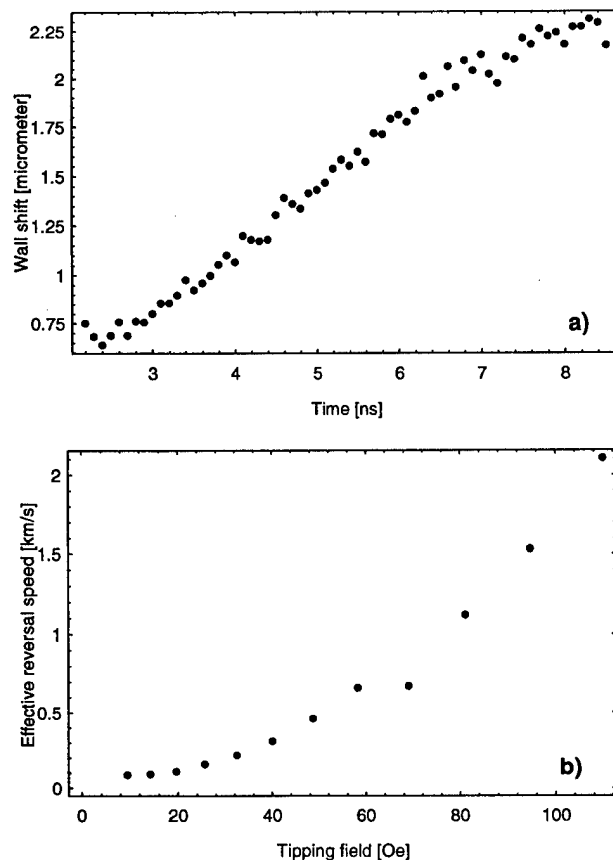

FIG. 7. (a) Wall shift as a function of time determined by integrating the reversed component along y in data as shown in Fig. 6(b). (b) The effective reversal speed as a function of tipping field amplitude, determined from the linear slope of curves as in (a).

As a function of the amplitude of the pulsed field, two distinct regimes are observed in the reversal dynamics of the initially antialigned domain. At smaller pulse amplitudes (less than ~ 60 Oe) the reversal proceeds via uniform motion of the central domain wall towards the edge of the bar. Characteristic data are shown in Fig. 6. Panel (a) is a snapshot of the magnetization change 5.5 ns after the onset of the pulse. The light area is the region that has been swept out by the moving domain wall. To see the progression in detail, the change in the longitudinal Kerr signal is shown in two dimensional images in Figs. 6(b) and 6(c) where the vertical axis corresponds to position along a line section through the center of the bar (in the short direction, y), while the horizontal axis is time. The signal growing with time in Fig. 6(b) for a small tipping field arises from motion of the domain wall with nearly constant velocity. The initial displacements of the wall are well below the spatial resolution of the microscope, so the rate of reversal is extracted by integrating the Kerr signal across the particle and plotting the integral as a function of time, as in Fig. 7(a). Normalizing the curve by the saturation signal divided by the width of the bar, the slope can be converted to a wall velocity.

Reversal rates as a function of pulsed field amplitude are shown in Fig. 7(b). A couple of points are of particular note. First, we do not observe a linear region at low fields, indicating that the motion cannot properly be described using a wall mobility. This may be indicating that we cannot ignore

FIG. 8. Time dependence of the x component of magnetization measured at sample center for three different structures, 4×4 , 10×4 , and $20 \times 4 \mu\text{m}$ (light, medium, heavy line, respectively). -35 Oe static field, tipping field amplitude $+140$ Oe. The dashed line shows the shape of the pulse, and the inset shows the rising edge response in more detail.

FIG. 9. The nonuniformity of response during the initial flip is shown in this set of magnetic images taken for the $10 \times 4 \mu\text{m}$ bar at $t = +3$ ns, under the conditions of Fig. 8. (a) Longitudinal (x) component. (b) Transverse (y) component. (c) Polar (z) component.

the influence of the closure domains at the ends of the bar on the motion of the wall. Second, at pulse amplitudes above 65 Oe, there is a nearly linear region, possibly preceded by a discontinuity in the curve. The images of the magnetization are qualitatively different in this regime, with the reversal proceeding not by movement of the domain wall but rather through a rotation process which propagates through the center of the domain after nucleating near the closure domain boundaries at the ends. This is clearly evident in Fig. 6(c), where change in the longitudinal Kerr signal is seen to begin not at the wall but closer to the center of the domain, and to develop symmetrically about this point. The distinct asymmetry arising from wall motion in Fig. 6(b) is notably absent. Therefore the reversal rates found at higher fields in Fig. 7 cannot correctly be interpreted as velocities because of this change in reversal mechanism. Normalizing the data as described above, the maximum wall speed we find before this phenomenological change is 650 m/s at 60 Oe.

A great richness of phenomena is observed upon pursuit of these investigations to higher fields. Beginning from an equilibrium state in which the centers of the bars are uniformly magnetized (static field of -35 Oe), we obtain a view of the speed of reversal by recording the time evolution of the magnetization change with the laser focussed at the center of the structure. Results are shown in Fig. 8 for $4 \mu\text{m}$ wide samples of three different lengths, 4, 10, and 20 μm . The 10 ns duration transient field has amplitude 140 Oe. The rising and falling transitions are markedly asymmetric, particularly for the longest and shortest samples. It is clear from the expanded view of the initial switch in the inset that reversal at the center occurs more rapidly for the shorter bars. The rise time of the pulse itself starts to become significant in limiting the speed for the $4 \times 4 \mu\text{m}$ structure.

Much more information is available in full time-resolved images of the magnetization. We observe that the reversal process starts with a wave-like spatial oscillation of the in-plane magnetization. Figure 9 has panels showing the three components of the magnetization (long. x , long. y , polar) for the $10 \times 4 \mu\text{m}$ particle at $t = 3$ ns after the onset of the field (see the abscissa of Fig. 8). The oscillation is initially quite

symmetric about the equilibrium (x) direction, and shows up most dramatically in the y component. One direction then grows at the expense of the other, culminating in reversal. The relative degree to which this behavior is related to the "concertina" structure seen in static reversal,¹⁴ or is induced by dynamics, remains to be sorted out. The wavelength of the spatial variation appears to be extremely stable and reproducible. At the same time these oscillations are clearly observed only on the rising edge of the pulses. Two effects may be at work to cause different behavior on the trailing edge. The time rate-of-change of the magnetic field is considerably less when the pulse shuts off relative to when it turns on, making it less effective at driving a dynamic instability. In addition the switched state may be more uniformly magnetized because of the unequal amplitudes of the static and transient fields, although the bar may not have completely relaxed into a switched equilibrium state by the end of the 10 ns pulse.

Strong dependences on sample size are also found in imaging. Some results from a more detailed investigation of magnetization reversal in the longer bar are reported in a companion paper.¹⁵

IV. DISCUSSION

The present work only begins to scratch the surface of what is possible with these pulsed optical methods. Many other materials systems and geometries remain to be investigated with our present set-up. Some of the choices will be guided by the desire for convergence between experiment and micromagnetic simulations, an obvious goal for the near term. The immediate goal is to study smaller particle sizes.

The same experimental techniques are well suited to the characterization of devices and media for magnetic recording, particularly when high speed is an issue.^{16,17} The utility of such measurements is further enhanced by time-domain magneto-optical measurements of currents, for direct comparison between the response (e.g., of the magnetization at the pole tips of a recording head) and the input (e.g., the drive signal to the coil). A stroboscopic "movie" of the magnetization at the air bearing surface of a write head in response to a dibit input can be viewed on the internet.¹⁸

In terms of the experimental method, there are many potential improvements that would further broaden the range of significant applications. Although the speed of the technique is more than adequate for our present studies, this is material dependent. Awschalom and co-workers⁴ have studied much faster dynamics in magnetic semiconductors using optical excitation of the sample. Substantial improvement of the speed of pulsed magnetic field generation is required before our approach can enter the sub-picosecond regime. Of even more interest is increasing the amplitude of magnetic field pulses, to open the door to large tipping angle measurements and associated nonlinearities in resonance. Studies of reversal in magnetically harder materials would also be of interest, as in the case of studies of high-speed switching in media by Doyle and co-workers.¹⁹ At present we are unable to pass more than about 300 mA peak current through the photoconductive switches. The corresponding current densities are very high and may be near to intrinsic damage thresholds of the materials, but the fact that the quantum efficiency of the devices is very low suggests that there may still be room for significant improvement here.

It is also imperative to improve spatial resolution in order to investigate the detailed micromagnetic dynamics of much smaller ferromagnetic particles. In the present experiments some information is already lost below the limit of spatial resolution, especially near the edges of the particles. When we attempt to cleanly separate the vector components of the magnetization the demands on resolution increase still further. Because of unwanted "clipping" of the beam which occurs as the focus spot scans over an edge, a small focus

also helps in keeping the entire laser spot on the particle as close to the edge as possible. We have developed a solid immersion lens capability for these experiments offering improvements of a factor of three in spatial resolution over that achieved here.²⁰ This is probably good enough to explore strong size effects and to be useful for the next few generations of magnetic devices, but certainly not for superparamagnetic particles or for such devices as seem certain to exist before the "endpoint" of magnetic recording is reached. In this regard the near-field and second harmonic generation methods of Silva, Rogers, and co-workers²¹ are particularly exciting.

Quantitative interpretation of a magnetic force microscopy (MFM) image usually requires detailed knowledge of the magnetization configuration of the sensing tip. Here, we demonstrated a technique that converts the obtained raw MFM image into the magnetic pole density distribution without explicitly knowing the tip magnetization orientation. By creating an approximate point source of magnetic poles in the same sample imaged, the impulse response function of the MFM tip is obtained for deconvolution of a raw image in the Fourier space. Experimental demonstrations with various tip magnetization orientations were performed on recorded magnetic transitions in a thin film longitudinal medium. © 1998 American Institute of Physics. [S0021-8979(98)53811-X]

I. INTRODUCTION

Magnetic force microscopy (MFM) has been used extensively in imaging magnetic structure in magnetic materials and devices. However, any MFM image depends on magnetization configuration of the sensing tip used, while the tip magnetization configuration can be very complicated. Lack of the knowledge of the tip magnetization orientation often results in difficulties in interpretation of the obtained images. Direct calculations on tip magnetization configuration have been undertaken, however, it is often intensive and requires detailed knowledge of the tip magnetic film microstructure.¹⁻³

A simple deconvolution technique has been proposed previously.⁴ However, using the ends of magnetized elongated narrow bar as an ideal magnetic pole point source presents many difficulties in practice. In this paper, a point source is created on the same sample imaged. The technique to convert a raw MFM image to the corresponding magnetic pole density distribution is presented in detail and demonstrated experimentally.

II. DESCRIPTION OF THE TECHNIQUE

A magnetic force microscope senses the gradient of the magnetic force exerted on the sensing tip due to the stray field of the sample. Assuming the measurement response is linear (which requires the tip magnetization be rigid), the obtained image $I(x,y)$ can be written as the convolution of the tip impulse response function and the magnetic pole density distribution, from which the stray field originates, as follows:⁴

$$I(x,y) = \int \rho(x',y') \cdot h(x-x',y-y') dx' dy', \quad (1)$$

where $\rho(x,y)$ is the magnetic pole density distribution in the sample and $h(x-x',y-y')$ is the tip impulse response func-

tion with tip at (x,y) and point pole source at (x',y') . The image for a point pole source at the origin is the tip impulse response function:

$$I_p(x,y) = h(x,y).$$

Using the impulse response function, a MFM image of a magnetic structure imaged with the same tip at the same imaging conditions, can be deconvolved in the Fourier space with a Wiener's filter:

$$\hat{\rho}(k_x, k_y) = \frac{\hat{I}(k_x, k_y)}{\hat{I}_p(k_x, k_y)} \cdot \frac{\hat{I}_p(k_x, k_y) \cdot \hat{I}_p^*(k_x, k_y)}{\hat{I}_p(k_x, k_y) \cdot \hat{I}_p^*(k_x, k_y) + \text{tiny}(k_x, k_y)}. \quad (2)$$

The final magnetic pole density distribution $\rho(x,y)$ can be obtained by inverse Fourier transformation of $\hat{\rho}(k_x, k_y)$. In all the cases presented here, $\text{tiny}(k_x, k_y)$ is chosen to be a small constant, adjusted for each individual case.

III. SIMULATION RESULTS

In this section, computer simulation results are presented to demonstrate the technique. In corresponding to the experimental demonstration, which will be presented in the later section, recorded transitions in a longitudinal thin film medium were chosen to be an example, as shown in Fig. 1. According to the orientation of the tip magnetization, three cases were shown here: the magnetization of the tip is case A: vertical, case B: horizontal, and case C: canted.

The track width is assumed to be $w = 2.0 \mu\text{m}$ and the intertransition spacing $B = 1.0 \mu\text{m}$. For calculation simplicity, the tip is assumed to be a uniformly magnetized sphere with diameter $D = 30 \text{ nm}$. The point source of the magnetic pole density is approximated by an isolated transition, i.e., $B = 16 \mu\text{m}$, with $W = 0.2 \mu\text{m}$. MFM images were calculated by calculating the gradient of the magnetic force exerted on the tip due to the stray field generated from the recorded transitions. The left height of the tip is $d = 60 \text{ nm}$.

^{a)}Electronic mail: lin@dilbert.ece.cmu.edu

FIG. 1. Recorded transitions for MFM imaging.

A. Case A: Tip magnetized vertically

In this case, the calculated image of the recorded transitions with assuming tip magnetization orientation is perpendicular to the sample surface, as shown in Fig. 2(a). In the image, alternating black and white stripes indicate the locations of the transitions. Since the magnetization in the tip is vertical, only the vertical component of the stray field contributes to the image. The image of the approximate point source is shown in Fig. 2(b). Using this image as the impulse function, the image shown in Fig. 2(a) was deconvolved in the Fourier space according to Eq. (2), shown in Fig. 2(c). The slight broadening of the images is due to the finite size effect of the approximated point source.

B. Case B: Tip magnetized horizontally

When the tip is magnetized horizontally, only the gradient of the horizontal component of the stray field is sensed. The MFM image of the same recorded magnetization structure becomes that shown in Fig. 3(a) as in contrast to that

FIG. 2. Calculated images with tip magnetization vertical to the sample surface. (a) Transitions, (b) point source, (c) deconvolved image.

FIG. 3. Calculated images with tip magnetization orientation horizontal. (a) Transitions, (b) point source, (c) deconvolved image.

shown in Fig. 2(a). The image of the approximate point source, shown in Fig. 3(b), also becomes dipolelike instead of a bell-shaped intensity profile as that shown in Fig. 2(b). Using this image of the point source to deconvolve the transition image in the Fourier space, the resulting magnetic pole density distribution is recovered, as shown in Fig. 3(c), almost exactly the same as that shown in Fig. 2(c).

C. Case C: Tip with magnetization canted

Since in practice, it is difficult to assure that the magnetization of the tip is either perfectly vertical or perfectly horizontal, the case of canted magnetization orientation was simulated. The canting angle in this case was set at 10° with respect to the horizontal. The calculated MFM image of the recorded transitions is shown in Fig. 4(a), which is essentially a mixture of Figs. 2(a) and 3(a). Figure 4(b) shows the image of the point source. The restored magnetic pole density distribution is shown in Fig. 4(c). Indeed, it is the same as that shown in both Figs. 2(c) and 3(c). The slight differences among the three restored pole density distributions are due to the finite size of the point source as well as the finite size of the sensing tip.

IV. EXPERIMENTAL RESULTS

Experimental demonstration was performed on a thin film longitudinal disk medium recorded with a thin film head. The track width was $W = 4.5 \mu\text{m}$ and adjacent transition separation was $B = 2.5 \mu\text{m}$. The point source was created by using the same thin film head used in the recording to dc erase the recorded isolated transitions from both sides of the track. For analysis on the effect of finite size point charge, the residual track width, i.e., the width of the point

FIG. 4. Calculated images with tip magnetization canted 10° with respect to horizontal. (a) Transitions, (b) point source, (c) deconvolved image.

charge, has been varied. The MFM tip has a magnetic coating thickness of 40 nm. The lift height of the tip during imaging was 60 nm.

Figure 5(a) shows the raw image of the recorded transitions with a vertically magnetized tip. Approximated point charges with various widths were used for image deconvolution. Figures 5(b), 5(c), and 5(d) show the deconvolved images for point charges of image widths 0.3, 0.46, and $0.55 \mu\text{m}$.

FIG. 5. MFM images with tip magnetized vertically (a) raw image (b)–(d): deconvolved images with different size point charges; (b) $0.30 \mu\text{m}$, (c) $0.46 \mu\text{m}$, (d) $0.55 \mu\text{m}$.

FIG. 6. MFM images with tip magnetized horizontally (a) raw image (b), (c): deconvolved images with different size point charges, (b) $0.30 \mu\text{m}$, (c) $0.55 \mu\text{m}$.

μm , respectively. For the case with the narrowest point charge, the resolution of the features in the deconvolved image is very similar to that in the raw image. Clearly, the wider the point charge width, the broader the feature size in the deconvolved images.

The same recorded transitions were imaged with the tip magnetized horizontally. The raw image is shown in Fig. 6(a). The deconvolved images with two different point charges of widths 0.3 and $0.55 \mu\text{m}$ (image widths), are shown as Figs. 5(b) and 5(c), respectively. The effect of finite size of the point charge is also evident.

V. SUMMARY AND REMARKS

We have experimentally demonstrated the deconvolution technique for removing tip dependence in MFM images and restoring the raw MFM image to the magnetic pole density distribution. By creating a point source on the same sample imaged, the impulse response function of the sensing tip can be obtained at the same imaging conditions. The technique does require that the magnetization of the tip is rigid during imaging. If the size of the point source is greater than the tip resolution, the resolution of the deconvolved pole density distribution will be degraded.

Since the MFM only senses the stray field from a magnetized sample, the formula by Madabhushi *et al.*⁵ is not valid. The divergence free portion of the magnetization M could not be recovered by MFM technique. Only the charge distribution can be imaged.

A method for calibrating the force gradients and probe magnetic moment in phase-contrast magnetic force microscopy (MFM) is introduced. It is based upon the combined electrostatic force microscopy EFM and MFM images of a conducting non magnetic metal strip. The behavior of the phase contrast in EFM is analyzed and modeled as a finite area capacitor. This model is used in conjunction with the imaging data to derive the proportionality constant between the phase and the force gradient. This calibration is further used to relate the measured MFM images with the field gradient from the same conducting strip to derive the effective magnetic moment of the probe. The knowledge of the phase-force gradient proportionality constant and the probe's effective moment is essential to directly quantify field derivatives in MFM images. © 1998 American Institute of Physics. I. INTRODUCTION

Magnetic force microscopy (MFM) has become a standard diagnostic workhorse in understanding surface magnetism. In its basic implementation, the technique maps an image which is proportional to the local magnetostatic force gradient between a ferromagnetic sample and a magnetic probe. In an ideal case of a magnetic dipole probe, the force F^m is the gradient of the magnetostatic energy, $(\vec{m} \cdot \vec{B})$, and the force gradient can be expressed as,¹

$$\frac{\partial F^m(x,y)}{\partial z} = \sum_{i=1}^3 \mu_0 m_i \cdot \frac{\partial^2 H_i(x,y)}{\partial z^2}. \quad (1)$$

The image depends upon the direction of the probe's magnetic moment, and contains the contribution of the different components of the surface stray field. In practice, it is customary to premagnetize the probe along the surface normal direction, \hat{z} , which makes the contrast proportional to the second derivative of the normal magnetic field component. By using Eq. (1), it is possible to interpret the images and extract the values of some parameters, such as the transition lengths and zigzag deviation of recorded patterns, the width of the domain wall, and the direction of local surface magnetization of ferromagnetic surfaces, as well as other quantities that are dependent only on the spatial coordinates but are independent of the absolute magnitude of the interaction force.² The difficulty in establishing the absolute values of the interaction force arises since the proportionality constant, K_p , between the measured oscillation phase, $\Delta\phi$ and the force gradient,

$$\Delta\phi = K_p \cdot \frac{\partial F_z}{\partial z} \quad (2)$$

is dependent upon the specific mechanical characteristics of the probe and its environment, and is generally unknown. In addition, the probe's effective magnetic moment, \vec{m} appear-

ing in Eq. (1) is also undetermined. Thus, without the knowledge of these two important probe-dependent parameters, Eq. (1) and Eq. (2) can only be taken as qualitative descriptions of the imaging contrast.

Several research groups have attempted to calibrate the probe and provide estimates for tip-sample interaction force. Unfortunately, due to space constraints in this article, we refer the reader to the literature. Previous approaches have involved the imaging of a standardized system, such as a metal strip^{3,4} or single-crystal surfaces⁵ or the usage of sophisticated methods to measure the magnetic moment of the probe and compare the acquired data with various models for the probe.^{6,7} There are, however, no methods that prescribe a self-contained calibration procedure of both the probe's mechanical and magnetic characteristics by utilizing only the measurements of the instrument itself. In this work, we propose a straightforward method for estimating K_p and m_z , thereby allowing a direct quantification of the MFM response. The basic concept uses the equivalence of the electrostatic (EFM) and magnetic interactions in generating the force gradients on a conducting metal strip. This was accomplished by imaging a test sample, an 11 μm wide Au metal line on silicon, using EFM and MFM with the same probe.

II. EXPERIMENTAL RESULTS AND DISCUSSION

The relationship between the force gradient and phase in Eq. (2) with constant K_p is valid as long as the scanned probe microscope (SPM) operates in a linear regime, which is tacitly assumed in our analysis. The force, F , could be due to either electrostatic or magnetostatic interactions. To determine K_p , we obtained an EFM image of the test sample by biasing the metal structure at voltage V relative to the probe at ground and examined the dependence of the phase contrast versus bias voltage and height. Note that a regular MFM probe was used for this experiment, since the magnetic coating is also electrically conducting. A typical EFM image is shown in Fig. 1 (right), along with a representative cross sectional profile. The electrostatic forces are purely attractive

^{a)}Electronic mail: rdgomez@eng.umd.edu

FIG. 1. Right: EFM image of a conducting 11 μm wide metal strip at $V = 2$ V. Left: MFM image of the same strip with 11 mA current. Bottom: Average line profiles across the strip.

so that the EFM contrast appears dark in the regions where the energized metal structure is present. The electrostatic force is a function of the bias voltage, V , as well as its capacitance:

$$F_z^e = -\frac{V^2}{2} \frac{\partial C}{\partial z}, \quad (3)$$

and the force gradient appearing in Eq. (2) can be expressed as

$$\frac{\partial F_z^e(x,y)}{\partial z} = -\frac{V^2}{2} \frac{\partial^2 C(x,y)}{\partial z^2}. \quad (4)$$

Equation (4) shows that the electrostatic force gradients and consequently the EFM images should vary as V^2 and its curvature and spatial variations are dependent only on the capacitance. This is experimentally verified in Fig. 2, which shows the acquired images at different voltages and at a constant height. The contrast has been reversed using software in order to emphasize the changing magnitude of the force gradient. In this experiment, the same area of the sample was continuously scanned at a tip height of 50 nm, as the bias voltage was progressively incremented by 100 mV. The values of the maximum phase contrast in the range from 100 mV to 2 V is shown at the bottom of Fig. 2. The fit to a quadratic function convincingly shows the V^2 dependence. As mentioned previously, all of the spatial variation in the electrostatic contrast is contained in the capacitance term so that the coefficient of the quadratic term in the fit is proportional to the second derivative of the capacitance with respect to z . Furthermore, since there are no dielectric materials in the gap region, the capacitance of the system depends only upon the geometrical arrangement.

To model the capacitance of the system, we considered the dependence of the image on the separation or the lift height, h , between the sample and probe. Figure 3 shows the variation of the image contrast at constant voltage, $V = 1.8$ V, as a function of the height, h . As in Fig. 2, the same region was imaged repeatedly, as the lift height was incremented to the labeled values. The glitch separating each increment is an instrumental artifact and arises due to the finite response time

FIG. 2. EFM contrast dependence on bias voltage. Top: EFM image at a lift height of 50 nm with increasing voltage. Bottom: Plot of the maximum contrast as a function of voltage, fitted to a quadratic function $\Delta\phi = 0.19V^2$.

of the feedback system. Nevertheless, the log-log plot of the maximum phase contrast versus h at the bottom of the image clearly shows the strong dependence of the phase image on h . The lines are various power law curves, and the best fit to the data is $\Delta\phi \sim h^{-1.9}$. The nearly h^{-2} dependence suggests that the interaction between the sample and probe can be modeled as a finite area parallel plate capacitor.

III. ANALYSIS

The capacitance for a square parallel plate capacitor can be solved using the Schwarz transformation technique⁸ and the second derivative with respect to the separation distance, h , is given by

$$\frac{\partial^2 C}{\partial h^2} = 2\epsilon_0 A \times \left(\frac{1}{h^3} + \frac{2}{\pi^{3/2} R h^2} \right), \quad (5)$$

where A is the effective surface area and R is the tip radius. In order to relate Eq. (5) with the parameters of the instrument, we assume that the apex of the pyramidal probe can be approximated by a square cross section of width $\sqrt{\pi}R$. The first term in Eq. (5) is identified with an infinite plate capacitor ($R \gg h$), and the second term is due to the fringing effects of the field at the edges. It is clear that as the sample-probe separation, h tends to zero, Eq. (5) is dominated by the first term. However, the relative contribution of the fringe effects increases as $0.36(h/R)$, so that the fringing field contributes about 36% for $R = h$ and significantly more for $h \gg R$. This is precisely the reason why the phase contrast in Fig. 3 follows the h^{-2} power law rather than h^{-3} . Substituting Eq. (5) into

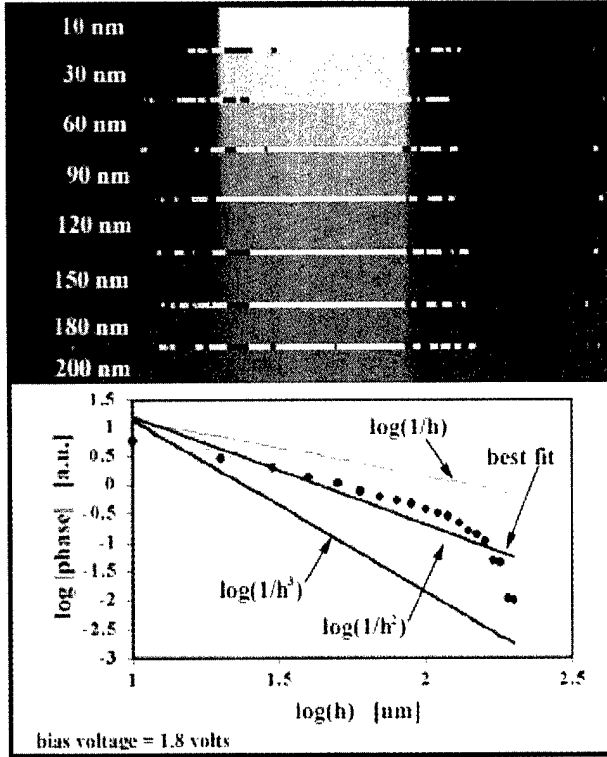

FIG. 3. EFM contrast dependence on lift height. Top: EFM image at a constant bias voltage of 1.8 V at varying lift heights. Bottom: Log-log plot of the maximum contrast as a function of height. Fit corresponds to $\log|\text{phase}| = -1.9 \log(h) + 3.1$; plots for $\log(1/h)$, $\log(1/h^2)$, and $\log(1/h^3)$ are also shown for comparison.

Eq. (4), and using the result into Eq. (2), yields the explicit expression for the calibration for the parameter, K_p .

$$K_p = 2 \left(\frac{|\Delta\phi|}{V^2} \right)_{\text{meas}} \bigg/ 2\epsilon_0 A \times \left(\frac{1}{h^3} + \frac{2}{\pi^{3/2} R h^2} \right), \quad (6)$$

where the numerator is the coefficient of the quadratic term of the data in Fig. 2, and the denominator is calculated directly from the parameters: $R=40$ nm, related to the effective tip curvature, and the lift height, $h=50$ nm. Inserting these numbers into Eq. (6) yields $K_p=369$ degs/Newton/m. Using this derived calibration constant, we can then calculate the effective probe moment along the z direction. In this case, we assume for convenience that the probe is nominally oriented along the z axis, so that only the z component of the surface stray fields contribute to the image. Again, we can make use of Eq. (1) and Eq. (2) to show that

$$m_z = \frac{\partial F^m}{\partial z} \bigg/ \frac{\partial^2 B_z}{\partial z^2} = |\Delta\phi|_{\text{meas}} \bigg/ K_p \frac{\partial^2 B_z}{\partial z^2}. \quad (7)$$

We now image the same current strip at a specific current, and measure the change in phase. A representative image is shown in Fig. 1(left), where the bright and dark contrasts are most pronounced at the edges of the strip as expected for the maximum normal field component. The field from this non-ferromagnetic current strip is well known and the field derivatives in Eq. (7) at a distance of $h=50$ nm and at a current of 11 mA is 5.5×10^{10} T/m². Using this value with the maxi-

mum measured phase of 0.045 degrees in Fig. 1 (left), we obtain the effective moment for the probe, $m_z = 2.22 \times 10^{-15}$ A m² (2.22×10^{-12} emu). This value is consistent with previous estimates,^{4,6} albeit somewhat lower, which could be attributed to differences on the specific probes used. As a plausibility check, we can compute the magnetization of the probe by dividing m_z with effective magnetic volume. If the effective volume is assumed to be that of a half-sphere ($2\pi/3 R^3$) with $R=40$ nm (film thickness at 40 nm as well) then the magnetization is in excess of 18 000 emu/cc, which is much larger than the 400–800 emu/cc remanent magnetization of the CoCr thin film coating. However, as pointed out by previous authors,⁹ the actual magnetic volume can be considerably larger than the volume of the half sphere shell at the apex of tip. In this particular case, if the effective volume were to include magnetic material up to a distance of 200 nm from the apex, then we obtain $M_p = 586$ emu/cc which is closer to the expected saturation magnetization of the CoCr coating.

In conclusion, the value of this calibration method is that the procedure is self-contained, and that all calibrations are derivable from the measurements themselves. It does not necessitate other sophisticated external measurements nor assumptions about the specific mechanical properties of the system. This will save considerable time and effort, and avoid the ever present doubt of whether the externally measured probe characteristics are invariant under actual operation. The procedure outlined in this paper, however, should be considered as an initial step that could be improved considerably. One area for improvement is the replacement of the analytical expression for the finite square area capacitor model with a more accurate numerical calculation involving the actual geometry of the pyramidal apex. This must be accompanied by a deconvolution procedure that takes into account the vertical excursion of the oscillating in the height-dependence measurements. Finally, it should be pointed out that while the calibration procedure here is carried out for phase-detection, a similar procedure can be performed for frequency or amplitude modes of force gradient mapping.

Magnetic force microscopy using nonoptical piezoelectric quartz tuning fork detection design with applications to magnetic recording studies

M. Todorovic and S. Schultz^{a)}

Department of Physics and Center for Magnetic Recording Research, University of California, San Diego, La Jolla, California 92093-0401

We have developed a novel form of magnetic force microscopy that uses a commercial piezoelectric quartz tuning fork to detect magnetic forces and force gradients. Such a detection system is extremely simple and inexpensive, compared to conventional optical methods of cantilever vibration detection. The setup is, in addition, characterized by small size, which makes it attractive for studies done in constrained spaces. The instrument is first described, then theoretical comparison of signal to noise ratio and resolution is made with the conventional optical detection techniques of cantilever vibration, and finally, first images of thin film media commercial hard disk magnetic bit transitions, point response of magnetoresistive elements, and field gradients above the write gap of a commercial hard disk head are presented. © 1998 American Institute of Physics.

[S0021-8979(98)28111-4]

I. INTRODUCTION

Magnetic force microscopy (MFM)¹ has become one of the most attractive techniques for studies of microscopic magnetic phenomena, and has found especially wide use in the commercial hard disk industry.² The simplicity of the technique and minimal sample preparation have furthered MFM popularity. In conventional MFM, the magnetic probe vibration is monitored by optical means, the most sensitive being the fiber optic interferometer.³ We have adapted piezoelectric quartz tuning forks (PQTF), first introduced by Karrai and Grober,⁴ as inexpensive and simple, nonoptical excitation and detection devices. The design is similar to the recent reports for near-field optical microscopy distance control,⁴⁻⁶ and dynamic AFM based on PQTF.⁷ We find PQTF are particularly effective for magnetic recording studies when proper modifications are made for detection of magnetic forces and force gradients. In Refs. 4-6, a tapered optical fiber is attached to one leg of the piezoelectric tuning fork, the tuning fork vibrates parallel to the sample surface, and the shear forces between the fiber end and the sample change the resonant properties of the fork. The signal is then mapped with respect to the position over the sample. This technique exploits the high Q of the PQTF, and the simplicity of the nonoptical, small sized, one component design. We have modified this setup by attaching a sharp magnetic tip to the end face of one of the legs of the PQTF, but vibrating in direction perpendicular to the sample, such that magnetic forces and force gradients can be imaged.

II. DESCRIPTION OF THE INSTRUMENT

To obtain maximum sensitivity of the instrument, we used the smallest available quartz tuning forks (Digi-Key Corp., Thief River Falls, Mn). The fork legs are 2 mm long, 200 μm thick, and 100 μm wide. This corresponds to a value of the spring constant, k , of approximately 2000 N/m, which

is an order of magnitude smaller than in previously reported shear force or dynamic AFM instruments. The Q is around 3000 in air and 35 000 in vacuum. To maintain the sensitivity, the magnetic probe is mounted on the end face of one of the tuning fork legs. This serves two purposes: (1) The quality factor, Q , of such a setup remains within a few percent of the initial Q of bare tuning fork, while the resonant frequency is reduced due to the added mass (see Fig. 1); and (2) This probe arrangement does not increase the spring constant of the tuning fork, thus keeping the sensitivity at a maximum. In a shear force microscope, due to specific probe characteristics, the fiber attachment usually reduces the Q from 7000 to 1000 and increases the spring constant, k , due to additional stiffness of the glue. Both of these changes reduce the sensitivity of the instrument.

In our tuning fork MFM, the magnetic probe is a sharp electrochemically etched nickel wire. Such probes are sometimes used in MFM work after being mounted on a piezoelectric bimorph and bent with a pair of sharp razors.⁸ In this new method, there is no need for bending the tip, which is often the hardest part of making such probes. The probe is

mounted, using micromanipulators under an optical microscope, on the end face of one of the legs of the tuning fork, which is initially covered with a small drop of glue. In addition, a small amount of silver epoxy connects the tip to one of the gold electrodes of the tuning fork in order to avoid electrostatic forces. The probe protrudes 100 to 300 μm from the edge of the tuning fork leg. In this completed form, shown in Fig. 2, the MFM sensor's overall height above the sample surface is less than 1 mm, which makes it very convenient for use in constrained spaces such as vacuum chambers, or under a lens of an optical or scanning electron microscope.

III. SENSITIVITY AND RESOLUTION CONSIDERATIONS

In conventional MFM, the vibration of the cantilever is monitored by optical means, and the signal that is measured is the second derivative of the field in the vibration direction. As the probe is scanned over a surface, the magnetic force gradients change the resonant frequency of the cantilever, and such change is detected in amplitude, phase, or frequency modulation modes, the last one having the largest bandwidth.⁹ The same physical principles apply in the tuning fork MFM design. The tuning fork is driven at the resonant frequency of approximately 32 kHz and magnetic force gradients are detected by monitoring the phase change in the resonant circuit. The sensitivity of the instrument is limited by the thermal noise of the tuning fork oscillator. In such case, previous publications have shown that the minimum detectable force gradient is proportional to¹⁰

$$\sqrt{k/Q\omega}.$$

Since conventional MFM cantilevers and PQTFs operate at similar frequencies, the differences between the two designs lie in spring constants and quality factors of the two respective mechanical oscillators. Regular MFM cantilevers have spring constants between 1 and 10 N/m and Q values of about 100 in air and 1000 in vacuum, while smallest tuning forks have k values of 2000 N/m and Q value of 3000 in air and 35 000 in vacuum.

The resolution of the MFM is determined by the dimensions and magnetic moment value of the probe, as well as the height at which it is scanned. For the highest resolution, minimum height is required, and a trade off is made with the spring constant to avoid tip crashes during the scan.¹¹ These comparisons make the conventional MFM more sensitive by a factor of less than 10, but the tuning fork can be scanned closer to the surface due to the larger spring constant.

IV. RESULTS AND DISCUSSION

Several types of measurements were done to demonstrate the usefulness of the simple design of tuning fork MFM in magnetic recording studies. The commercial hard disk recorded transitions were imaged in air, as shown in Fig. 3. The tuning fork was positioned near the sample surface by a vertical mechanical translator. The fork tines were vibrating at amplitudes between 25 and 50 nm, as confirmed independently by the fiber-optic interferometer³ we use in conventional MFM work. The sample was scanned by a high precision, linearized piezoelectric stage. The image in Fig. 3 was taken in the phase mode and the scan range is 5 μm . As expected, the image shows equivalent resolution to the conventional MFM, since the dimensions of the tip are similar. The signal-to-noise ratio compared to conventional MFM image is lower by an order of magnitude, which is also expected theoretically due to the larger spring constant of the tuning fork.

In addition to imaging magnetic transitions on hard disk media, the tuning fork MFM has also been used for measuring the point response function of commercial magnetoresistive elements,¹² and imaging field gradients above the write gaps of commercial heads.¹ The head was placed on the

FIG. 3. 5 μm \times 5 μm scan of hard disk magnetic transitions with 2.8- μm -track width.

FIG. 4. Block diagrams for (a) MR point response measurement, (b) write gap imaging.

sample holder so that the MR element and write gap face the tip on the tuning fork as shown in Fig. 4. The tuning fork was first driven at resonant frequency while over the MR element, thereby providing a magnetic alternating point flux source. The driving signal to the tuning fork was used as a reference signal for the lock-in amplifier, which monitored the signal from the MR element. Simultaneous with monitoring the ac MR element signal, a second lock-in amplifier monitored the signal from the resonant tuning fork circuit in order to avoid tip crashes during scan. Figure 5 shows the resulting image. The specific features of the MR point response function were repeatable.

Alternatively, the inductive write head was driven at the resonant frequency of the tuning fork, as shown in Fig. 4(b). Alternating field gradients from the gap exerted alternating forces on the tip, and the piezoelectric signal from the tuning fork was monitored with a lock-in amplifier. Figure 6 shows the field gradient gray scale image of the trimmed pole write gap. These techniques provide important information about MR sensor cross track response, field gradients above the gap, and could provide simple and inexpensive diagnosis during fabrication of MR heads.

In conclusion, novel detection technique for magnetic force microscopy is described and applications to magnetic

recording technology are presented. The technique provides an inexpensive, simple, and small sized alternative to conventional MFM.

Kerr effect enhancement by photon tunneling and possible application to a new scanning probe magnetic microscope

A. Kikitsu^{a)} and C. M. Falco

ARL/Surface Science Division, The University of Arizona, Tucson, Arizona 85721

M. Mansuripur

Optical Sciences Center, The University of Arizona, Tucson, Arizona 85721

Magneto-optical effects are calculated for the film stack consisting of hemisphere glass/magnetic film (10 nm)/air gap (d nm)/glass plate. Polarized light (wave length=800 nm) is irradiated through the hemisphere glass in the total internal reflection configuration. A typical amorphous rare earth-transition metal alloy is used for the magnetic layer. We find a large monotonic change in the figure of merit (product of the reflected amplitude of light and the Kerr rotation angle) as a function of the air gap, ranging from 1 to 800 nm. Similar results are obtained for a magnetic film with a 10 nm SiO₂ protective layer and for a 1-nm-thin magnetic film. This phenomenon is mostly caused by a change in the reflectivity at magnetic film/air interface due to photon tunneling. The difference in the figure of merit between perpendicular and longitudinal magnetization is about 0.6°. These results imply that it might be possible to obtain an image of perpendicular magnetic moment with photon scanning tunnel microscopy (STM). This method can be combined simultaneously with a conventional atomic force microscope or STM. © 1998 American Institute of Physics. [S0021-8979(98)53511-6]

I. INTRODUCTION

In the total internal reflection (TIR) mode, light irradiated from the first medium with refractive index n_1 to the second medium with n_2 ($n_1 > n_2$) is completely reflected at the boundary,¹ and the electromagnetic field in the second medium, which is called an evanescent field, decreases exponentially with the distance from the boundary. However, when a third medium with refractive index n_1 exists close to the first medium, the evanescent wave is converted to a propagating wave at the second boundary. This phenomenon is called photon tunneling.² The photon scanning tunnel microscope (STM)³ utilizes this phenomenon. A scanned fine tip is used as the third medium, and the morphology of the first boundary (distance from the tip) is detected as a change in the intensity of the converted light.

When the incident light is linearly polarized and the first medium is a magnetic film, magneto-optical (MO) effect, that is, a rotation of the polarization angle, will be observed both in the reflected and the converted light and also will be changed with the distance from the tip. This leads to a scanning probe magnetic microscope, which has the advantages of being sensitive to low magnetization materials and having no magnetic interaction between probe and sample. Safarov *et al.* reported such a microscope using a pulsed magnetic field to a Co thin film sample.⁴ However, no static magnetization image was reported. A weak MO signal in the converted light appears to be a problem in this microscope system.

In this article, we calculate MO effects in a hemisphere glass/magnetic film/air gap/glass plate system in the TIR

condition and estimate them from the view point of the figure of merit, which corresponds to the detected intensity. Then we discuss the possibility of a new scanning probe magnetic microscope using the photon tunneling phenomenon.

II. CALCULATION

Numerical calculations were performed by the program MULTILAYER^{TM5} with a configuration shown in Fig. 1. This program solves Maxwell's equations at flat interfaces without any approximations. A linearly polarized light (wave-length 800 nm) irradiated through the hemisphere glass at an angle θ greater than the critical angle. The values of the dielectric tensor of a typical amorphous rare earth-transition metal alloy with perpendicular and longitudinal magnetization were used for the magnetic layer.

III. RESULTS AND DISCUSSION

A change in the figure of merit [(FOM): $E \times \theta_k$, E : amplitude of light, θ_k : Kerr rotation angle] of the reflected light

FIG. 1. Configuration used for the calculations.

^{a)}Permanent address: Materials and Devices Research Laboratories, Toshiba Corporation R&D Center, Kawasaki, Kanagawa 210, Japan. Electronic mail: akira.kikitsu@toshiba.co.jp

FIG. 2. Figure of merit (=amplitude $\times\theta_k$) of the reflected light vs the air gap for glass/MO material (10 nm)/air (d nm)/glass plate. P -polarized incident light and perpendicular magnetization were assumed.

against the air gap d for $\theta=60^\circ$, 70° , and 80° is shown in Fig. 2. The magnetic film is a perpendicular magnetized MO material with thickness of 10 nm. The incident beam has a unit intensity and is p polarized, that is, the direction of the polarization is perpendicular to the film surface. Although a large θ_k , more than 2° , is obtained at a couple of specific conditions, E tends to be small in such cases, so the FOM is small. As can be seen, the FOM increases monotonically with decreasing d . For $\theta=60^\circ$, the change in the FOM is as large as 0.6° , which is larger than the FOM for the case of normal incidence of 0.13° . The result for the longitudinal magnetization is shown in Fig. 3. FOM has rather complex d dependence but the change in the FOM is less than 0.1.

It is clear that the detected MO signal almost corresponds to the perpendicular magnetic moment from the results of Figs. 2 and 3. A difference in the FOM between perpendicular and longitudinal magnetization cases is shown in Fig. 4. When the direction of an analyzer is set to be crossed to that of the polarization for large d case, the signal intensity becomes large with decreasing d . Therefore, it might be possible to utilize this phenomenon for a new scanning probe magnetic microscope by using a fine glass tip instead of the glass plate.

The change in FOM is caused by the change in the reflectivity at magnetic film/air interface according to the extent of photon tunneling. That is, FOM changes from the value of glass/magnetic film/glass configuration ($d=0$) to that of TIR configuration ($d=\infty$). In the calculation of FOM, a contribution of multiple-beam interference within magnetic film and air gap is included. When a fine glass tip is used for the glass plate in Fig. 1, such an interference does not expect to occur. However, FOM change is not thought to decrease so much even when the tip completely scatters the

FIG. 3. Figure of merit vs d , for the longitudinal magnetization case.

evanescent wave. FOM from hemisphere glass/magnetic film interface is estimated to be $+0.1^\circ$ and that from magnetic film/glass interface ($d=0$) is estimated to be more than 0.03° for $\theta=60^\circ$. Since FOM for large d value is independent of the occurrence of the scattering, FOM change is expected to be more than 0.57° for $\theta=60^\circ$.

Though a possible problem is that almost all of the detected light comes from the area where the tip is not positioned, this light can be eliminated when the direction of an

FIG. 4. Difference in FOM between the perpendicular and longitudinal magnetization cases for glass/MO material (10 nm)/air (d nm)/glass.

FIG. 5. The difference in FOM between the perpendicular and longitudinal magnetization cases for the case of $\lambda=633$ nm, for magnetic film with 10 nm SiO_2 protective layer and for 1 nm magnetic film. Conditions are p -polarized incident, $\theta=60^\circ$ and perpendicular magnetization.

analyzer is set as mentioned above. As for the case of collecting the evanescent wave, large FOM (about 0.3° at maximum) is obtained but it includes much contribution of the multiple-beam interference in air gap and also this method has a problem of poor coupling efficiency between photon and glass probe. Moreover, our method could employ a couple of signal enhancement method such as an ac method with photoelastic modulation optics⁶ or by vibrating the tip.

Since a tip need not collect the light, a metal tip can be used. A change in FOM with air gap for glass/magnetic film/air/Pt is 0.5° . This means that simultaneous measurement of

magnetization and morphology would be possible by combining our method with a conventional STM or atomic force microscope.

In order to examine the feasibility of this method, MO effects were calculated for various film configurations. Figure 5 shows the results for 633 nm wavelength, for a magnetic film with a 10 nm SiO_2 protective layer and for 1 nm magnetic film. Similar results to that shown in Fig. 4 are obtained. This method is useful for magnetic film with a dielectric overcoat and might have the capability for ultrathin magnetic film.

IV. SUMMARY AND CONCLUSION

A magneto-optical effect for the film stack of hemisphere glass/magnetic film/air gap/glass plate is calculated in the total internal reflection condition. It is found that the figure of merit (FOM) of reflected light changes monotonically as a function of the air gap. This phenomenon is caused by the change in the reflectivity at magnetic film/air interface due to photon tunneling through the air gap. The monotonic air gap dependence of FOM and a FOM difference as large as 0.6° between perpendicular and longitudinal magnetization are found, so it might be possible to apply this phenomenon to a new scanning probe magnetic microscope.

Design and construction of a sensitive nuclear magnetic resonance force microscope

T. A. Barrett, C. R. Miers, H. A. Sommer, K. Mochizuki, and J. T. Markert^{a)}

Department of Physics, University of Texas, Austin, Texas 78712

We report our progress in the design and construction of a sensitive and versatile nuclear magnetic resonance force microscope. Improvements over previous designs include the use of higher Q ($Q \approx 10^5 - 10^7$), single-crystal double-torsional mechanical oscillators for force detection and the development of extremely convenient positioning and approach capabilities. We describe both a demonstration experiment using large (~ 1 cm) torsional oscillators and the micromachining of the small ($\sim 100 \mu\text{m}$) torsional oscillators. © 1998 American Institute of Physics.

[S0021-8979(98)49711-1]

I. INTRODUCTION

Recently, Rugar *et al.*¹ have reported the force detection of nuclear magnetism. In such an experiment, shown schematically in Fig. 1, the nuclear spins, in a sample mounted on a mechanical oscillator, are first polarized in a large static magnetic field; the z component of the nuclear magnetism is cyclically inverted at the mechanical oscillator resonant frequency by a modulated radio-frequency field from a nearby coil. This time-dependent nuclear moment is coupled to the field gradient of a nearby permanent magnet, producing a resonant force on the mechanical oscillator; the oscillator motion is detected with a fiber-optic interferometer. Here, we first describe the probe that brings these elements together; we then discuss the design sensitivity of this probe. The function of the elements is demonstrated using large single-crystal silicon double-torsional oscillators; finally, the fabrication of the torsional micro-oscillators that will permit the ultimate design sensitivity is discussed.

II. EXPERIMENT

The experimental probe, contained in a vacuum can, fits in a 60-mm-diam variable-temperature cryostat which itself is inserted in the bore of an 8.2 T superconducting magnet. The bottom of the probe is shown in Fig. 2. Rotary motion

from outside the probe drives the three mechanical translators shown, one each for fiber coarse approach positioning, oscillator lateral movement, and permanent magnet positioning. The piezoelectric elements provide finer adjustments: the piezoelectric bimorph swings the fiber optics in and out

FIG. 1. Experimental setup for the NMR microscope, including static field B_0 , inhomogeneous field magnet, double-torsional oscillator, rf field coil, and fiber-optic interferometer.

FIG. 2. Probe elements showing manipulation capabilities: three translators for coarse positioning, and piezoelectric bimorph, tube, and stack for fine positioning.

FIG. 3. The single-crystal silicon double-torsional oscillator. In the antisymmetric mode, most of the energy is in the motion of the head.

of the plane of the figure, the stack piezo provides fiber optic fine positioning, and the tube piezo provides fine positioning for the permanent magnet.

Fiber optic interferometers of similar design have been described elsewhere.² Here, a 675 nm laser diode is coupled into one arm of a Gould directional coupler; reflections from the cleaved end of the fiber and from the nearby oscillator interfere and are sensed by a PAR photodiode, the output of which is detected by a lock-in amplifier. For this system, the output current at the photodiode is about 20 pA/Å; the photodiode noise level is less than 0.2 pA/√Hz, thus providing a motion sensitivity of better than 0.01 Å/√Hz.

We refer to Ref. 1 for a discussion of detailed relations between the relevant quantities. Here, we specify the parameters used in our demonstration experiment: the static field was varied (as the permanent magnet approached a paraffin sample at the edge of the oscillator) over the range of 8.50–8.55 T (8.20 T from the superconducting magnet, and 0.30–0.35 T from an iron-wire permanent magnet). An approximately 20 G rf field was turned on 400 kHz off resonance, swept to the NMR frequency of 363.5 MHz over a 0.5 ms period, and then frequency modulated at the oscillator 10.3 kHz frequency with an amplitude of 50 kHz. The static field gradient at the sample was approximately 300 T/m.

For both the demonstration experiment and for the ultimate microscope design, single-crystal double-torsional oscillators are used. To understand why, refer to Fig. 3. Residual losses in single-crystal oscillators occur through coupling to the base; typical cantilever modes have a $Q \approx 10^3$. For a double-torsional oscillator in the antisymmetric mode with a small moment of inertia at the top (the head), most of the energy is stored in the head, effectively isolating its Q . We routinely obtain Q 's of $\sim 10^5$ at room temperature, $\sim 10^6$ at 77 K, and $\sim 10^8$ at 4.2 K. For any mechanical oscillator, the theoretical sensitivity from thermal noise is $F_{\min} = \sqrt{4kk_B T \Delta \nu / Q \omega}$, where ω and k are the frequency and effective spring constant of the oscillator. For our large os-

FIG. 4. Amplitude of motion of oscillator head during the NMR experiment described in the text.

cillators at room temperature, the measured parameters indicate $F_{\min} = 3 \times 10^{-13}$ N. However, this produces a motion a factor of five smaller than our photodiode detection limit of 0.01 Å/√Hz; thus the latter sets the noise level. For our small oscillators, we predict $F_{\min} = 2 \times 10^{-18}$ N at 4.2 K; this, however, will result in a motional amplitude of 0.2 Å, well above our photodiode limit; thus for the small oscillators, the noise is thermally limited.

In the one-dimensional experiment using the large oscillators, no signal is observed at the lock-in output when the spins in the sample are far from resonance. As the magnet approaches the sample, there reaches a point where a slice of the spins are resonant, of thickness $\Delta z = \Delta B / (\partial B_z / \partial z)$,¹ where $\Delta B \approx 20$ G is determined by the frequency modulation and the amplitude of the rf field. For our $\partial B_z / \partial z \approx 300$ T/m, we have $\Delta z \approx 7$ μm. Thus for our 2-mm-diam sample, a volume of 0.02 mm³ was resonant, corresponding to 6×10^{17} spins and a moment (via Curie's law) of 6×10^{-14} J/T, and thus a force of $F = M(\partial B_z / \partial z) = 2 \times 10^{-11}$ N, well above our photodiode noise floor. Figure 4 shows a plot of the lock-in output as a function of time for a 1.3 s rf pulse; the oscillator is seen to ring up to an amplitude of approximately 0.25 Å before decaying back to the noise level of approximately 0.01 Å, indicating a force of about 3×10^{-11} N, quite close to the predicted value.

For the small oscillators, the moment sensitivity will be greatly enhanced, both because of the increased force sensitivity and because much larger field gradients can be used (the maximum field gradient simply scales inversely with the diameter of the wire). For example, a 100-μm-diam wire will produce a field gradient of about 10^4 T/m, implying a resolvable moment of 10^{-21} J/T, or about 10^9 proton moments at 4.2 K. Such NMR sensitivity is unprecedented.

III. OSCILLATOR FABRICATION

The oscillators were fabricated by standard photolithographic and micromachining techniques. The large oscillators have been described elsewhere.^{3,4} The small oscillators were fabricated as follows: a silicon wafer was masked with

FIG. 5. Scanning electron micrograph of one of the micro-oscillators.

rows of various sizes of micro-oscillators, typically $150\ \mu\text{m}$ high, and implanted with 134 keV boron ions at a dose of at least $1.4 \times 10^{16}/\text{cm}^2$ to provide an etch stop for the final structures. This implant was chosen for a target depth of $4000\ \text{\AA}$ and initial profile thickness of approximately $1000\ \text{\AA}$. The implanted wafers are then annealed at $1000\ ^\circ\text{C}$ for 15

min to 4 h to recrystallize the damaged silicon and spread the profile to any desired thickness up to about $4000\ \text{\AA}$. The annealed wafers were placed in an anisotropic silicon etch consisting of 48% H_2O , 32% ethanol, and 20% KOH for about two days. Once the oscillators were fully undercut from the substrate, a great impediment to completing the fabrication is the drying (surface tension tends to pull the oscillators to the substrate). To overcome this, a freeze-drying technique⁵ was successfully employed, eliminating the surface tension problem completely. Figure 5 shows an scanning electron microscopy (SEM) micrograph of the free-standing single-crystal double-torsional micro-oscillator attached only at the base. Such oscillators are now undergoing characterization and testing for use in the NMR microscope.

Exchange-spring behavior in epitaxial hard/soft magnetic bilayer films

J. S. Jiang,^{a)} Eric E. Fullerton,^{b)} M. Grimsditch, C. H. Sowers, and S. D. Bader

Materials Science Division, Argonne National Laboratory, Argonne, Illinois 60439

We present results on the magnetic reversal process in epitaxial Sm-Co(1100)/TM (TM=Fe, Co) bilayer films prepared via magnetron sputtering onto Cr-buffered single-crystal MgO substrates. The magnetically hard Sm-Co films have 20 T uniaxial anisotropy and coercivities >3 T at room temperature. The magnetization of the soft layer is pinned at the interface to the hard-magnet layer and switches reversibly as expected for an exchange-spring magnet. With increasing soft layer thickness, the coercive field of the hard layer becomes significantly less than that of a single layer. We also present numerical solutions to a one-dimensional model that provide the spin configuration for each atomic layer. Comparison of the experimental results with the model simulations indicates that the exchange-spring behavior of our bilayer films can be understood from the intrinsic parameters of the hard and soft layers. © 1998 American Institute of Physics.
[S0021-8979(98)42611-2]

The exchange-spring magnets, which are composed of suitably nano-dispersed hard and soft magnetic phases, have been the subject of many recent studies.¹⁻⁸ Exchange interaction between the two magnetic phases results in enhancement of the remanence and the energy-product. Although future application of exchange-spring magnets will most likely be based on nano-dispersed composite geometries,⁸ to obtain greater insights into the coercivity mechanism and magnetization reversal process in these materials, it is advantageous to devise a simpler structure with well-defined properties to isolate the various contributions that are often masked by the structural complexities of a random two-phase system. Theoretical calculations by Skomski and Coey^{6,7} predicted that, in superlattice structures consisting of exchange coupled soft layers and aligned hard-magnet layers, a giant energy-product of 120 MGOe (about three times that of commercially available permanent magnets) is attainable.

It is now possible to fabricate high-quality permanent magnet thin films with well-defined crystallographic orientation and close-to-intrinsic magnetic properties.⁹ For example, epitaxially grown Sm-Co films can have the *c* axis of the hcp structure lying in-plane, giving rise to strong uniaxial in-plane anisotropy.¹⁰ These films, when incorporated into the bilayer structure with transition metal (TM) soft-magnet layers, provide a model system in which the magnetization rotation process of the exchange-coupled TM layers can be studied with the applied field both parallel and perpendicular to the anisotropy axis of the hard layer. In this article we examine the magnetization reversal processes in epitaxial hard/soft Sm-Co(1100)/TM bilayers (TM=Fe and Co). We also use a simple one-dimensional atomic model to simulate

the spin profile and the magnetization hysteresis loops. Comparison of the experimental results with the model simulations indicates that the exchange-spring behavior can be understood from the intrinsic parameters of the hard and soft layers.

The Sm-Co(1100)/TM bilayers are grown via dc magnetron sputtering onto single-crystal MgO(110) substrates coated with an epitaxial 200 Å Cr(211) buffer layer. The 200 Å Sm-Co layers are deposited by co-sputtering from separate Sm and Co sources with a nominally Sm₂Co₇ concentration at a substrate temperature $T_S = 600^\circ\text{C}$ as outlined in Refs. 9 and 10. The TM layers are then grown at $T_S = 300\text{--}400^\circ\text{C}$ with thicknesses of 25–200 Å and capped with a 50 Å Cr layer. The magnetic properties were measured using a 7 T superconducting quantum interference device (SQUID) magnetometer equipped with both longitudinal and transverse coils, and the longitudinal magneto-optic Kerr effect (MOKE) using *p*-polarized, 633 nm light.

The structural and magnetic characterization of Sm-Co(1100) films grown onto Cr(211) buffer layers are described in detail in Ref. 10. The epitaxial relation for the Sm-Co(1100) films is $\text{Sm-Co}[0001] \parallel \text{Cr}[01\bar{1}] \parallel \text{MgO}[001]$, resulting in a uniaxial in-plane structure with the magnetic easy axis parallel to the Sm-Co *c* axis. The films exhibit strong uniaxial in-plane anisotropy consistent with the expected *c*-axis anisotropy. For **H** parallel to the Sm-Co easy axis (MgO[001]), a square loop is observed with a coercive field H_C of 3.4 T. The coercivity increases to 7.3 T at 25 K. For **H** applied in the orthogonal in-plane direction, a sheared hard-axis loop is measured. The anisotropy field, estimated from extrapolating the hard-axis loop to saturation, is ≈ 20 T, close to the known anisotropy value of bulk Sm-Co. These high-quality hard magnetic layers form the basis of this study.

Shown in Fig. 1 are room-temperature easy-axis hysteresis loops of the Sm-Co(200 Å)/Fe bilayers with different

FIG. 1. Room-temperature magnetic hysteresis loops for single layer Sm-Co and Sm-Co/Fe bilayer films with different Fe thickness with H parallel to the easy-axis directions. The loops are offset vertically for clarity.

Fe layer thicknesses. For a 25 Å Fe layer, a square easy-axis loop is measured, indicating that the Fe layer is strongly coupled to the underlying Sm-Co film and that the two layers switch as a unit. As the result of coupling between the layers, the coercivity $H_c = 1.7$ T is only $\sim 50\%$ of that of the isolated Sm-Co film. For the 100 and 200 Å Fe layers the loops change shape quite significantly, and separate switching transitions for the Fe and Sm-Co layers are observed. This is similar to that observed in Refs. 11–14 but with much thinner soft layers in the present samples. The switching fields for the Sm-Co layers (0.6–0.7 T) are similar for the 100 and 200 Å Fe layers and are only 20% of that of the isolated Sm-Co film value. The saturation magnetization M_s increases with increasing Fe layer thickness.

FIG. 2. Room-temperature magnetic properties of Sm-Co/Fe bilayer films measured by MOKE. (a) Hysteresis loop (solid curve) and recoil curves (open circle) measured with H parallel to the easy-axis directions for the 100 Å Fe film. (c) The irreversible magnetization ΔM_{irr} vs reverse field measured with H parallel to the easy axis.

Shown in Fig. 2(a) are the hysteresis loop and recoil curves for the 100 Å Fe layer film measured using the MOKE technique. As a result of the finite penetration of the light, the MOKE measurements are dominated by the top Fe layer. At low reverse fields, the Fe layer is pinned by the underlying Sm-Co layer. The Fe layer starts to switch at the exchange field $H_{ex} = 0.22$ T. Above H_{ex} , a sharp drop in the magnetization occurs as the Fe layer starts to rotate away from alignment with the hard layer. The rotation is fully reversible since the recoil curves coincide with the demagnetization curve. At reverse fields > 0.5 T, the recoil curves deviate from the demagnetization curve as the hard layer begins to switch irreversibly and the Fe does not recover full remanence on recoil. A quantitative assessment of the irreversibility is the irreversible magnetization change $\Delta M_{irr} = M_r - M_d(H)$ where M_r is the remanent magnetization and $M_d(H)$ the field-demagnetization remanence after recoiling from the reversal field H . Shown in Fig. 2(b) is $\Delta M_{irr}/2M_r$ as a function of the reverse field. The magnetization is fully reversible ($\Delta M_{irr} = 0$) up to 0.5 T, where the Sm-Co layer switches and ΔM_{irr} begins to increase sharply.

To obtain greater insight into the switching of both the soft and hard layers, we use a one-dimensional atomic model where the bilayer is treated as a chain of spins normal to the layers and each spin is the sum of total moments in an atomic layer.^{11,13,15} The total energy of the system is given by:

$$E = - \sum_{i=1}^{N-1} \frac{A_{i,i+1}}{d^2} \cos(\theta_i - \theta_{i+1}) - \sum_{i=1}^N K_i \cos^2(\theta_i) - \sum_{i=1}^N H M_i \cos(\theta_i - \theta_H), \quad (1)$$

where the rotation angle for the i th layer θ_i is measured relative to the easy-axis direction of the hard layer, θ_H is the angle between the field and the easy axis, A_i , K_i , M_i , d are the exchange constants, uniaxial anisotropy constants, magnetic moments, and inter-plane distance ($= 2$ Å), respectively. The equilibrium spin configuration for a given field is determined by minimizing Eq. (1). To calculate this configuration we employ an iterative approach outlined by Camley.¹⁶ Details of the modeling will be published elsewhere.¹⁷

Shown in Fig. 3(a) is a comparison of the calculated Sm-Co/Fe(200 Å) demagnetization curves to the ones measured at 25 K. Included are both the longitudinal and transverse magnetization with respect to the applied field. The parameters used in the calculation are, for the hard layer, $A_h = 1.2 \times 10^{-6}$ ergs/cm, $K_h = 5 \times 10^7$ ergs/cm³, $M_h = 550$ emu/cm³; for the soft layer, $A_s = 2.8 \times 10^{-6}$ ergs/cm, $K_s = 10^3$ ergs/cm³, $M_s = 1700$ emu/cm³, the interface exchange constant $A_{int} = 1.8 \times 10^{-6}$ ergs/cm, and $\theta_H = 3^\circ$. The values of K_h and M_h were estimated from magnetization measurements on the Sm-Co films. The calculation reproduces the H_{ex} value, the field dependence of both the longitudinal and transverse magnetization, as well as the switching field of the Sm-Co layer at ≈ 1.5 T. The value of A_{int} , which is intermediate to the exchange coupling of the hard and soft layers, reflects the strong interfacial exchange cou-

FIG. 3. (a) Low-temperature (25 K) demagnetization curves for the Sm-Co/Fe(200 Å) film compared to the model calculation (solid line). The longitudinal and transverse components of the magnetization are given by the circles and triangles, respectively. (b) Representative spin configuration determined from the model calculation shown in (a). Open circles are Fe spins and filled circles are Sm-Co spins. The free Fe surface is located at zero and the Sm-Co/Fe interface is at 200 Å.

pling between the layers. With a large interfacial exchange energy, the moments in the soft layer near the interface are pinned by the hard layer. Shown in Fig. 3(b) is the spin configuration at various fields for the calculated magnetization in Fig. 3(a). As expected, the distribution of moments is consistent with the expectation that the Fe located away from the interface rotates more. As H increases, the interfacial Sm-Co spin is also increasingly rotated and a domain wall is slowly introduced into the hard layer. At a field such that the domain wall energy density in the soft layer becomes greater than that in the hard layer, the domain wall in the soft layer moves into, and switches, the hard layer.¹

The temperature dependence of the Sm-Co(200 Å)/Co(100 Å) bilayer is shown in Fig. 4. At low temperatures, separate switching transitions are observed for the Sm-Co and Co layers at H_{irr} and H_{ex} , respectively. The exchange field for the bilayer structure with Co layers is significantly higher than that with Fe layers of comparable thickness. This behavior arises from the intrinsic magnetic anisotropy of the Co layer. The c -axis Co anisotropy stabilizes the Co layer either parallel or antiparallel to the Sm-Co film and results in an enhanced Co switching field. The Co layer reverses by nucleating a 180°-domain wall. As long as the Sm-Co does not switch, the H_{ex} is given by the requirement that the energy cost (γ) in creating a domain wall be balanced by the gain in Zeeman energy ($HM_s t$), i.e., $H_{ex} = \gamma/M_s t$, where t is the Co layer thickness. A rough estimate gives $H_{ex} \approx 0.7$ T, in reasonable agreement with the experiment. The exchange field H_{ex} remains rather temperature-insensitive whereas the H_{irr} decreases with increasing temperature, suggesting that the hard layer switches via some thermally assisted reverse domain nucleation and wall de-pinning. At temperatures above 250 K, square easy-axis loops are observed as the Sm-Co and Co layers switch simultaneously a nucleation field H_N .

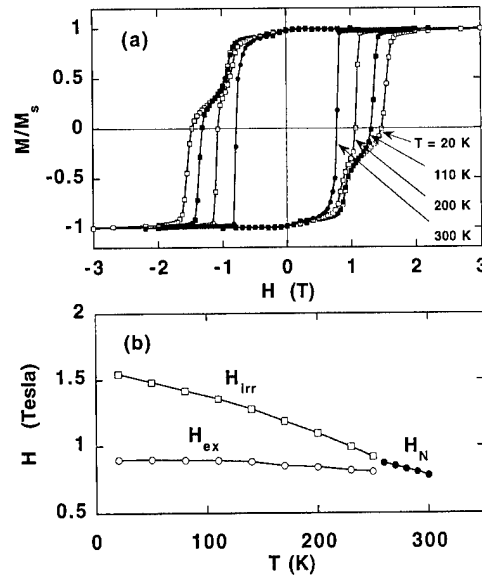

FIG. 4. (a) Easy-axis hysteresis loops for the Sm-Co(200 Å)/Co(100 Å) measured at different temperatures. (b) The switching fields plotted as a function of temperature.

In conclusion, we have presented the experimental results on strongly exchange-coupled Sm-Co(1100)/TM bilayer films. The magnetically hard Sm-Co layers have an in-plane uniaxial anisotropy field as large as 20 T. The magnetization of the soft TM layer is pinned at the interface to the hard-magnet layer and switches reversibly as expected for an exchange-spring magnet. Our model calculation using intrinsic parameters gives quantitative agreement with the experimental data.

Magnetization reversal of Nd(Dy)–Fe–B thin films on Si(111) or Ta/Si(111)

J. L. Tsai, T. S. Chin,^{a)} and E. Y. Huang

Department of Materials Science & Engineering, Tsing Hua University, Hsinchu 300, Taiwan, Republic of China

S. K. Chen

Department of Materials Science, Feng Chia University, Taichung 407, Taiwan, Republic of China

Nd(Dy)–Fe–B films were prepared by dc magnetron sputtering on a Si(111) wafer with or without a Ta underlayer. The reversal magnetization process of Nd–Fe–B/Ta bilayer was found to be dominated by nucleation control model with the magnetic inhomogeneity coefficient $\alpha_k=0.32$ defined by Kronmuller's formulation of micromagnetic theory. But the coercivity mechanism of Nd(Dy)–Fe–B single layer was fitted well to domain wall pinning behavior. The range factor (half width between pinning sites) r_0 is equal to 6.9 nm as $r_0 > \delta_B$, the width of the domain wall. The magnetization phenomena of the two films are also manifest from initial magnetization curves.

I. INTRODUCTION

Nd–Fe–B films have been prepared by thin film processes such as magnetron sputtering, molecular beam epitaxy, and pulsed laser deposition.^{1–4} These films have potential applications in microelectronics or the micro-electromechanical system (MEMS) due to the high energy product possible even down to a nanometer scale. The magnetic properties depend mainly on microstructure, thus the growth technologies, texture control, and microstructure studies of Nd–Fe–B films have attracted much attention.^{5–11}

Magnetization reversal of Nd₁₅Fe₇₇B₈ sintered magnets and Nd–Fe–B melt spun ribbons has been studied in detail by Kronmuller using the micromagnetic model,^{12–14} and by Hadjipanayis using the Gaunt model,¹⁵ respectively. But that of Nd–Fe–B thin films has not been studied in-depth so far due mainly to the difficulty in structure control and the interface problems.

In this article we applied Kronmuller's formulation to study the coercive mechanism of the sputtered Nd(Dy)–Fe–B films with or without the Ta underlayer, which has been reported to exhibit exchange interaction between the interface.¹⁶

II. EXPERIMENT

Nd(Dy)–Fe–B films, with a thickness of 324 nm, with or without a Ta underlayer (30 nm) were prepared by dc magnetron sputtering carried out in a vacuum chamber with a background pressure of 5×10^{-7} Torr. A commercial Nd₁₂Dy₃Fe₇₇B₈ target and a pure Ta foil, with a diameter of 3.3 cm each, were used. The distance between the target and the substrate was 10 cm. High purity argon (99.999%) was used as a sputtering gas and the working pressure was 8×10^{-3} Torr during sputtering. The Nd(Dy)–Fe–B films were deposited at room temperature and post annealed in a high vacuum (1×10^{-7} Torr) with a temperature between 480 and 600 °C. The phases of films were analyzed by x-ray

diffraction (XRD). The thickness of each film was measured using an α -step thickness probe. The surface roughness of the films was measured with an atomic force microscope (AFM). The initial magnetization curves and magnetic hysteresis loops with different applied fields were measured with a vibrating sample magnetometer (VSM) at room temperature. The magnetic properties of the films were also measured at 5–400 K by a superconducting quantum interference device (SQUID) magnetometer under a maximum field of 55 kOe.

The coercive mechanism was studied by using the modified Brown's micromagnetic theory.¹²

III. RESULTS AND DISCUSSION

A. Microstructure study

Figure 1 shows the x-ray diffraction patterns of Nd(Dy)–Fe–B films with or without Ta underlayer. All peaks are attributed to R₂Fe₁₄B single phase (refer to JCPDS file 39-0473, where R is the rare-earths) for both the (Nd,Dy)₂Fe₁₄B single layer and the (Nd,Dy)₂Fe₁₄B/Ta bilayer. The Ta diffraction cannot be found because of its extreme thinness, about 30 nm. The (Nd,Dy)₂Fe₁₄B peaks are rough and broadened due to the fine grain structure resulting from the lower annealing temperatures at 480–520 °C for 10 min.

To make a quantitative surface morphology, the root mean square surface roughness was taken by an AFM to be 4.8 and 8.9 nm, respectively, for the films with or without Ta underlayer. Samples with roughness below 10 nm appear to have a mirrorlike smoothness which is good for application in lithography.

B. Initial magnetization curves

Figure 2 shows magnetic hysteresis loops of films with or without the Ta underlayer measured parallel to the film plane. The coercive force of the (Nd,Dy)₂Fe₁₄B single layer and the (Nd,Dy)₂Fe₁₄B/Ta bilayer are 14.0 and 11.3 kOe, respectively, while the squareness ratio of the bilayer, 0.72, is higher than that of the single layer, 0.62. The shape of

^{a)}Electronic mail: tschin@mse.nthu.edu.tw

FIG. 1. X-ray diffraction patterns of sputtered (Nd,Dy)₂Fe₁₄B films on Si(III).

hysteresis loops changes as the magnetization field is increased. Initial magnetization curves of the (Nd,Dy)₂Fe₁₄B film with or without the Ta underlayer exhibit two different magnetization reversal processes; that of (Nd,Dy)₂Fe₁₄B/Si(111) film, sustaining nearly the same width before a sharp ascent, is dominated by the domain-wall pinning,¹⁷ while that of the bilayer shows neither a nucleation nor a wall-pinning control process, as shown in Fig. 2(a). Thus further testimony was carried out by the micromagnetics approach.

C. Testimony of the magnetization reversal model

According to the well-known micromagnetic approach, the relationship between coercivity (H_c) and the ideal nucleation field (H_n) is given by Brown's formula¹⁸

$$H_c = \alpha H_n - N_{\text{eff}} M_s. \quad (1)$$

Here α is a form factor and H_n equals $2K_1/M_s$, corresponding to the ratio between the first anisotropy constant and spontaneous magnetization, respectively. N_{eff} means effective local demagnetization factor. A modified relationship about form factor α has been derived from the micromagnetics theory by Kronmüller,^{13,14,19} describing the reduction in nucleation field due to (1) the misalignment of grains α_φ ; and (2) the magnetic inhomogeneity coefficient α_k i.e., $\alpha = \alpha_\varphi \alpha_k$

$$H_c = 2K_1 \alpha_\varphi \alpha_k / M_s - N_{\text{eff}} M_s. \quad (2)$$

For the studied Nd₁₂Dy₃Fe₇₇B₈ films, the R₂Fe₁₄B hard magnetic phase possesses K_1 values from negative to positive in the temperature range 5–400 K. The temperature dependent coercive force of the films could be delineated in two parts:

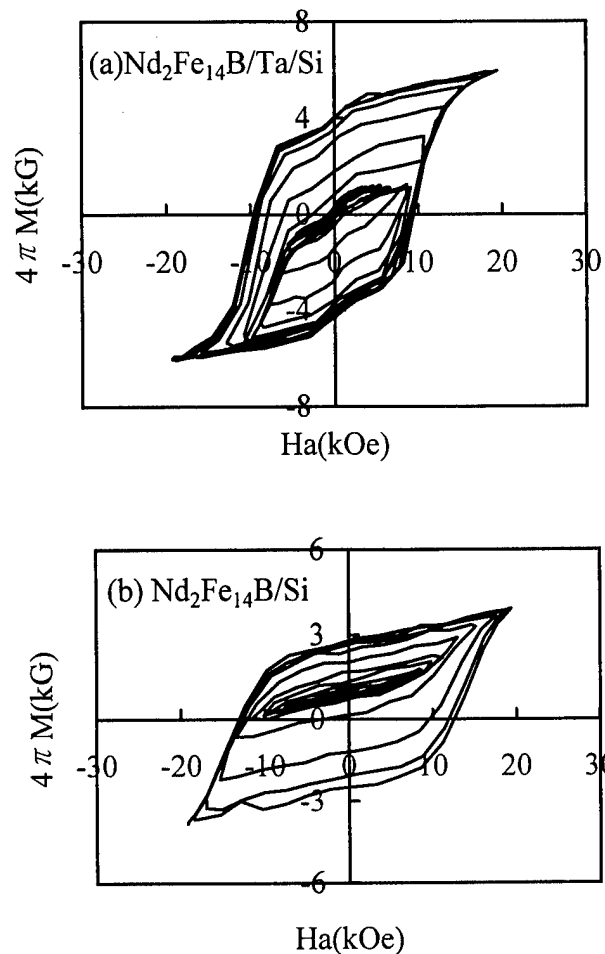

FIG. 2. Hysteresis loops of (Nd,Dy)₂Fe₁₄B films at different applied fields.

one below the spin reorientation temperature ($T_{\text{sr}} \approx 135$ K) and the other above it. Three temperature ranges are distinguishable:²⁰

- (i) In the temperature range of 5–135 K: ($K_1 < 0, K_2 > 0$)

FIG. 3. H_c/M_s vs $2K_1 \alpha_\varphi / M_s^2$ for the sputtered (Nd,Dy)₂Fe₁₄B film with Ta underlayer.

FIG. 4. H_c/M_s vs $2K_1\alpha_\phi/M_s^2$ for the sputtered $(\text{Nd,Dy})_2\text{Fe}_{14}\text{B}$ film without Ta underlayer.

$$H_c = 2K_1\alpha_\phi\alpha_k/M_s - N_{\text{eff}}M_s \quad (2')$$

$$\alpha_\phi = \frac{1}{\cos \delta [1 + (\tan \delta)^{2/3}]^{3/2}} \left(1 + \frac{3K_2(\tan \delta)^{2/3}}{K_1[1 + (\tan \delta)^{2/3}]} \right),$$

where δ is replaced by $\delta = \phi + \theta$ for $K_1 < 0$. Without the external field, the easy magnetization direction deviates from the c axis by an angle $\theta = \arcsin(-K_1/2K_2)^{1/2}$, if spin reorientation occurs for $K_1 < 0$.¹²

In the temperature range of 135–298 K:

$$(K_1 > 0, K_2 > 0, -K_2 < K_1 < 4K_2) \quad (3)$$

$$H_n = \frac{4(K_1 + K_2)}{3M_s} \left(\frac{1}{3} + \frac{K_1}{6K_2} \right)^{1/2}.$$

In the temperature range of 298–400 K:

$$(K_1 \gg K_2, K_2 > 0)$$

$$H_n = 2K_1/M_s \quad (4)$$

$$\alpha_\phi = \frac{1}{\cos \phi [1 + (\tan \phi)^{2/3}]^{3/2}} \left(1 + \frac{3K_2(\tan \phi)^{2/3}}{K_1[1 + (\tan \phi)^{2/3}]} \right),$$

where ϕ is the angle between the c axis of neighboring grains. The α_ϕ is equal to 0.5 for isotropic $\text{Nd}(\text{Dy})\text{-Fe-B}$ thin films.

As indicated in Eqs. (3) and (4), in both case $H_n\alpha_\phi/M_s$ vs H_c/M_s should be fitted in a straight line for a nucleation control magnet. The plot of $H_n\alpha_\phi/M_s$ vs H_c/M_s is shown in Fig. 3. The linearized slope is the value of α_k , which in this case is measured to be 0.32, being larger than the critical value of 0.30. The effective demagnetization field N_{eff} is obtained as 0.45. This means that the coercive mechanism of

$\text{Nd}(\text{Dy})\text{-Fe-B}$ film with the Ta underlayer is dominated by the nucleation control model. By using Eq. (2'), the fitting of H_n/M_s vs H_c/M_s is also a line but with a negative N_{eff} that is out of physical meaning. The data of $\text{Nd}(\text{Dy})\text{-Fe-B}$ film without the Ta underlayer were also fitted by Eqs. (3) and (4).

By measuring magnetic properties of $\text{Nd}(\text{Dy})\text{-Fe-B}$ single layer film from 5 to 400 K, a linear plot of H_c/M_s vs $2K_1\alpha_\phi/M_s^2$ was obtained as shown in Fig. 4. The magnetic inhomogeneity coefficient α_k is measured to be 0.12. This value is less than the critical value of 0.3. Therefore, the magnetization reversal of the $\text{Nd}(\text{Dy})\text{-Fe-B}$ single layer film is determined by domain-wall pinning. A magnet with a thick pinning region of ($r_0 > \delta_B$) should have an α value of ($2\delta_B/3\pi r_0$), where r_0 is a range factor (half-width between pinning sites). The reported data of domain wall width δ_B was equal to 3.9 nm for the $\text{Nd}_{15}\text{Fe}_{77}\text{B}_8$ sintered magnet.²¹ The calculated value of r_0 is 6.9 nm.

Co-Sm and Co-Pr films were deposited by dc magnetron sputtering. Transmission electron microscopy and magnetic measurement were used to study the microstructure and magnetic property relationship. The nanostructure of the as-deposited Co 19 at. % Sm films consists of two phases: the amorphous phase and the crystallite phase. Upon annealing at 600 °C, the Co₅Sm phase with the Cu₅Ca structure, having grain size of about 20 nm, is obtained along with high coercivity (45 kOe). The as-deposited Co 22 at. % Sm films also have nanostructure similar to the Co 19 at. % films except the volume fraction of the crystallite is reduced. This is related to the concentration of Sm which promotes the formation of the amorphous phase. A new metastable phase Co₃Sm is formed upon annealing of the Co 22 at. % Sm film at 500 °C. This phase has the DO₁₉ structure in which the Sm atoms take ordered positions of a triangular pattern in the close-packed planes. A relatively high coercivity value of 29 kOe was obtained from this phase. The as-deposited Co-Pr films show mainly an amorphous phase. Upon annealing at 500 °C for 20 min, Co₂Pr with the Mg₂Cu-type structure was identified in the Co 35 at. % Pr film. Two phases were identified in the Co 16 at. % Pr films. Coercivities up to 3.1 kOe were achieved in these films. © 1998 American Institute of Physics. [S0021-8979(98)30611-8]

I. INTRODUCTION

Hard and semihard Co rare earth films are of increasing interest for magneto-electronic and magnetic-recording applications. The Co-Sm and Co-Pr systems also have high T_c suitable for high temperature magnets. A number of articles on the Co-Sm and Co-Pr systems have been presented.¹⁻⁵ The magnetic properties of materials can be divided into intrinsic properties and extrinsic properties. The intrinsic properties such as magnetization are related to the crystal structure of the magnetic phase while the extrinsic properties such as coercivity are affected by the microstructure. Development of new magnetic materials involves the search for new magnetic phases and the design of microstructure. In this article we report our detailed study on phase formation, microstructure, and magnetic properties relationship in films based on the Co-Sm system and Co-Pr system heat treated at different temperatures.

II. EXPERIMENTAL PROCEDURE

For the Co-Sm system, the films were deposited by dc magnetron sputtering. Two compositions near the Co₅Sm and Co₇Sm₂ were selected. All films have a Cr underlayer of about 90 nm except the one with the composition of Co 19 at. % Sm annealed at 600 °C which is deposited on a quartz substrate. All the films have a Cr cover layer of about 10 nm. For the Co-Pr system multilayers of Co-Pr/Co films were deposited using a multiple-gun dc and rf sputtering chamber. The multilayer microstructure is designed to promote magnetic hard phase and soft phase coupling in order to gain maximum energy product. A 50 nm underlayer and a 10 nm

cover layer of Cr were used for film seeding and protection. Plan-view transmission electron microscopy (TEM) samples were prepared by dimpling and ion milling process. TEM study was conducted using a JEOL 2010 transmission electron microscope.

III. RESULTS AND DISCUSSION

The deposition parameters, film thickness, coercivity, and phase identification results are summarized in Table I.

FIG. 1. Magnetization loop of the Co₅Sm film annealed at 600 °C.

TABLE I. Composition, deposition condition, nanostructure, and magnetic properties relation in Co–Sm and Co–Pr films. C indicates crystallite phase and A amorphous phase. Vc is the volume fraction of the crystallite phase against the amorphous phase.

Film com. (at. %)	Ar pressure (mTorr)	Film thickness (nm)	Phases	Vc (%)	Grain size (nm)	Coercivity (kOe)
Co 19 at. % Sm	5	24	C+A	91	5	0.61
Co 19 at. % Sm	12	24	C+A	65	5	2.58

FIG. 2. (a) Comparison of SAD pattern and calculated intensity distribution for the film described in Fig. 1. (b) TEM image of the microstructure.

FIG. 3. (a) Comparison of SAD pattern and calculated intensity distribution for the Co 22 at. % Sm film. (b) TEM image of the microstructure.

The nanostructure of the as-deposited Co 19 at. % Sm films has been studied in earlier work¹ and is included here for comparison. Upon annealing at 600 °C, the equilibrium phase Co₅Sm with the Cu₅Ca structure is obtained along with high coercivity. Figure 1 shows the magnetization loop. Coercivities up to 45 kOe were achieved. Figure 2 shows the selected area diffraction (SAD) pattern and TEM micrograph. The diffraction shows perfect match with the calculated intensity. The grain size is about 20 nm.

The Co 22 at. % Sm films also have a nanostructure similar to the Co 19 at. % films except the volume fraction of the crystalline against amorphous phase is reduced. This is related to the concentration of Sm which promotes the formation of the amorphous phase. Figure 3 shows the SAD pattern and the TEM image of the Co 22 at. % Sm film annealed at 500 °C. A new phase Co₃Sm is formed as indicated by the matching of the TEM pattern and calculation. This phase has the DO₁₉ structure in which the Sm atoms taking the ordering positions of a triangular pattern in the close-packed planes. The close-packed planes are stacked by the sequence of ABAB in the *c* direction. A relatively high coercivity value of 29 kOe was obtained from this phase.

The appearance of the DO₁₉ structure is not a surprise but rather easy to comprehend. In the as-deposited Co–Sm films, the structure of the crystallite is the close-packed structure with Sm atoms randomly distributed in the close-packed planes and short range packing order in the *c* direction. Upon annealing, two things happened: one is that the Sm atoms within each close-packed plane form a triangular ordering pattern, and the second is that the packing in the *c* direction takes the long range ABAB packing. The lattice parameters deduced from this phase are $a=0.256$ nm $c=0.419$ nm compared to the lattice parameters of Co $a=0.2505$ nm, 0.4065 nm. It is interesting to note that the lattice parameters between the DO₁₉ phase and the Co phase are close to each other, suggesting a low energy state at the interphase. It is suggested that two-phase structure composed of Co and DO₁₉ phase could be stable up to 500 °C.

The as-deposited Co–Pr films show largely amorphous phase. Upon annealing at 500 °C for 20 min, Co₂Pr of the Mg₂Cu-type structure was identified in the Co 35 at. % Pr film. Two phases were identified in the Co 16 at. % Pr films. Coercivities up to 3.1 kOe were achieved in these films.

IV. CONCLUSIONS

Three metastable phases were found in the sputtered Co–Sm films: the amorphous phase, the close-packed hexagonal phase with different stacking mode in the as-deposited film, and the DO₁₉ structure phase in the film annealed at 500 °C.

Corresponding to the different phases and microstructure, the coercivities change from about 1–42 kOe. Maximum coercivity was achieved from the Co₅Sm phase with the Cu₅Ca structure. The new metastable phase of DO₁₉ structure found in the Co 22 at. % Sm film also showed relatively high coercivity of 29 kOe.

High coercivity SmCo based films made by pulsed laser deposition

F. J. Cadieu,^{a)} R. Rani, X. R. Qian, and Li Chen

Department of Physics, Queens College of CUNY, Flushing, New York 11367

Films of SmCo based materials exhibiting high intrinsic coercivities and smooth hysteresis loops have been prepared by pulsed laser deposition (PLD) onto moderately heated substrates. Films directly crystallized from SmCo₅ targets onto 375 °C substrates exhibited a maximum $H_c = 11.3$ kOe at a pulse repetition rate of 10 Hz with lower coercivities for both lower and higher pulse repetition rates. In the present case the films were deposited onto polycrystalline substrates. The films exhibited a very small grain size of less than 1 μm diameter, were mirrorlike, and shadow deposited films were relatively particulate free under scanning electron microscope examination. Shadowed PLD deposition was used for the best films. Laser wavelengths of 193 and 248 nm were used with pulse repetition rates from 5 to 50 Hz. Films grown without shadowing exhibited a great deal of particulate contamination. The hysteresis loops of such nonshadowed films were constricted and exhibited drops in the $4\pi M$ values upon demagnetization. To our knowledge this is the first reporting of high coercive force SmCo based films deposited by PLD exhibiting single phase type hysteresis loops. © 1998 American Institute of Physics. [S0021-8979(98)42811-1]

INTRODUCTION

High coercivity films of SmCo based systems have been deposited by sputtering by several distinct variants. Highly textured polycrystalline films have been made by using sputter process control to grow films at thicknesses out to at least 120 μm .¹⁻⁴ Such films have the crystalline c axes nearly randomly aligned onto the substrate plane. Buffer layers are necessary to grow relatively thick films but in principle arbitrarily thick films of highly aligned SmCo deposits can be grown by this method. In contrast to this, highly aligned thin films with thicknesses of less than 0.1 μm have been grown by using substrate film epitaxy.^{5,6} The thicker films as grown by sputter process control are generally more suited to device applications. Such relatively thicker films as grown by sputter process control have been used to bias to saturation YIG substrates,⁴ to bias permalloy films,⁷ and in the construction of a film based magneto-optic waveguide isolator.⁸ In this latter device the textured SmCo films were grown directly onto compliant layers directly deposited onto a Bi-YIG optical waveguide so that epitaxy could not have been used to grow such films. Film scale magnetic devices generally employ a magnetically sensitive material such as a magnetoresistive material, a superconducting film element, or a magnetic field sensitive optical material. In addition soft magnetic films are used as flux paths with permanent magnet films used as magnetic biasing elements. Many of the magnetically sensitive types of materials have been readily deposited by pulsed laser deposition (PLD). Such films include high T_c oxide superconductors, ferrites, and magnetoresistive materials such as the La manganites. It should be noted that these are oxide materials which are generally difficult to sputter deposit with controlled texturing and at appreciable deposition rates. To illustrate the differences in PLD and sputter deposition we have made SmCo based magnetic films by PLD. Although the time averaged deposition rates of

sputter and PLD deposited films are comparable, material is ejected in PLD only during a series of pulses of very short time duration compared to the time between pulses.⁹ This means that the relative mobility of deposited surface atoms is very much less for PLD than for sputtering since a complete monolayer can be deposited per pulse. The growth of PLD deposited permanent magnet films also has direct impact on the fabrication of film scale magnetic devices. There have been only a few reportings of rare earth transition metal films as grown by PLD and mostly confined to Nd₂Fe₁₄B.¹⁰

EXPERIMENT

PLD, utilizing a Lambda Physik 305Fi excimer laser, has been used to deposit SmCo based films from a set of bulk compound targets. Films have been deposited using wavelengths of 248 and 193 nm, pulse energies of 500–650 mJ at 5–50 Hz with an estimated pulse width of 15 ns. A shadow mask has been used to shield part of the substrate during the PLD process. In this manner the magnetic properties, as well as the number of particulates reaching the substrate in and out of the shadow region, could be observed. Most of the films discussed here have been grown using a substrate temperature ranging from 100 to 750 °C in argon pressures from 100 to 240 mTorr. Film compositions were determined using electron excited x-ray analysis in a scanning electron microscope (SEM). The film composition measurements were calibrated against known bulk composition standards.

RESULTS AND DISCUSSION

SmCo based films deposited by PLD in the absence of any shadowing onto heated alumina substrates exhibited a strong dependence of Sm concentration on the argon background gas pressure in the deposition chamber. Figure 1 shows the Sm concentration for a series of films deposited onto polished alumina substrates at 375 °C from SmCo₅ targets, and at 500 °C from SmCo “2–17” targets, as a func-

^{a)}Electronic mail: Fred_Cadieu@QC.EDU

FIG. 1. The Sm at % for a series of PLD films made on to 375 °C substrates from bulk SmCo_5 targets, and films made on to 500 °C substrates from bulk SmCo "2-17" targets, for different Ar pressures during the deposition is shown.

tion of Ar gas pressure. The targets in the latter case consisted of normal bulk type "2-17" magnet material with a composition of Sm 13 at %, Co 58%, Fe 20%, Cu 7%, and Zr 2%. Under vacuum conditions the film Sm concentration corresponded to that of the targets. Films made under vacuum, however, exhibited a large number of particulates causing such films to be unattractive for film device applications. During sputtering large concentration changes can also be effected by using increased sputtering gas pressures and in particular admixtures of Xe as a part of the sputtering gas.² Changes in the sputtering gas pressure could be used to vary the film composition from 12 to 18 at %.¹¹ Higher pressures tend to preferentially scatter the lower mass transition metal atom components relative to the more massive Sm atoms. The net effect is that the lighter transition metal atoms are on the average scattered through larger angles and effectively removed from the deposition beam. Higher pressures in the deposition chamber tend to enrich the Sm concentration in the films.

Room temperature hysteresis loops measured in plane and perpendicular to the plane are shown in Fig. 2 for a shadow region film deposited at 375 °C and 100 mTorr Ar at a laser wavelength of 193 nm with a pulse rate of 14 Hz. The PLD target was bulk SmCo_5 . The in plane H_c was 9.7 kOe and the loop shape was characteristic of single phase material. It should be noted that there is no retracing of the in plane hysteresis loop to the highest measurement magnetic field of 18 kOe. An x-ray diffraction pattern for the film of Fig. 2 is shown in Fig. 3. The evident CaCu_5 -type structure (110) dominant texturing and (111) secondary CaCu_5 -type shoulder are consistent with the relative shapes of the in plane and perpendicular to the plane hysteresis loops.

Films of SmCo based materials made without the use of a shadow mask exhibited an appreciable density of particulates on the substrate. Films made in vacuum, 1.8×10^{-7} Torr, on to 550 °C substrates exhibited a small grain size of 0.17–0.30 μm diameter. The particulates tended to be of two principal sizes, $\approx 0.33 \mu\text{m}$ diameter for the small ones, and $\approx 0.83 \mu\text{m}$ diameter for the larger ones. The particulate density for nonshadowed films increased with pressure even though the number density of the larger sized par-

FIG. 2. Room temperature hysteresis loops for a shadow deposited PLD film made from SmCo_5 target at 375 °C on to alumina substrate, pressure 100 mTorr Ar, pulse rate 14 Hz are shown. The key items to note are that the intrinsic coercivity is 9.7 kOe and that the loop shape is smooth.

ticulates remained nearly constant. Nonshadowed films made at 500 °C and 30 mTorr Ar exhibited an average particulate density of $0.21/\mu\text{m}^2$, similar films except at 75 mTorr Ar exhibited $0.33/\mu\text{m}^2$. In order to limit the number of particulates arriving at the substrate a stainless steel sheet metal shadow was located in the deposition plume to block the direct transport of particulates to the substrate. A higher background gas pressure of argon was then required to scatter the atoms to reach the substrate. The shadow mask strip was arranged midway between the target and substrate so that the shadow blocked a 13×50 mm substrate region.

Figure 4 shows hysteresis loops for a SmCo based film shadow deposited at a substrate temperature of 375 °C in 100 mTorr Ar at a laser pulse rate of 10 Hz. The in film plane H_c was 11.3 kOe. The film surface was mirrorlike which is different from directly crystallized textured SmCo films grown onto alumina films by sputtering. The smooth mirrorlike surface was consistent with a small average grain size. The

FIG. 3. An x-ray diffraction trace for the film of Fig. 2 is shown which indicates (110) dominant and (111) secondary texturing. The x ray is indexed as CaCu_5 -type structure film. The substrate lines from the polycrystalline Al_2O_3 are indicated by S in the figure.

FIG. 4. Room temperature hysteresis loops are shown for a PLD film deposited from bulk SmCo_5 target at 375°C , pressure 100 mTorr Ar, shadowed deposition. The laser settings were 193 nm, 600 mJ pulses, 10 ns pulse width, and 10 Hz.

shadow deposited films replicated polish marks on the underlying substrate that made it difficult to determine a film grain size. The deposit in the shadow region was particulate free.

To study the effects of surface atom mobility a series of films were deposited from bulk SmCo_5 targets in 100 mTorr Ar onto substrates held at 375°C using $\lambda=193$ nm for differing pulse repetition rates from 5 to 50 Hz. This is shown in Fig. 5 where the H_c values versus laser pulse rate are shown for a series of films shadow deposited under the same conditions except for the laser pulse repetition rate. The higher pulse rates result in low coercivities due to insufficient time between pulses for surface atom site adjustments.

FIG. 5. The coercivity H_c vs laser pulse rate is shown for a series of films shadow deposited from SmCo_5 bulk targets using $\lambda=193$ nm, T substrate $=375^\circ\text{C}$, and $P=100$ mTorr Ar. The values shown were measured at room temperature on as deposited films.

In this series the highest coercivity of 11.3 kOe was obtained for a pulse rate of 10 Hz. The hysteresis loops for films made at laser pulse rates between 10 and 20 Hz were offset in the initial magnetization direction since the maximum applied field of 18 kOe was insufficient to achieve saturation. Lower pulse rates resulted in low coercivities believed to be caused by surface gas contamination due to the longer times between successive pulses.

A key result of this article is that it has been possible to produce SmCo films directly by shadowed PLD onto slightly heated substrates with coercivities up to 11.3 kOe at 10 Hz as a function of the laser pulse repetition rate. Higher laser pulse rates did not allow sufficient site relaxation between pulses, while lower pulse rates lead to film contamination because of the longer time between deposition pulses. An operative deposition condition is that $\sqrt{T}/R = \text{const} \cdot d$, where T is the absolute substrate temperature with the surface atom speed proportional to \sqrt{T} , d is the site relaxation distance, and $1/R$ is the time between laser pulses for the pulse rate R . Higher laser pulse rates can then only be fruitfully used at higher substrate temperatures where the surface atom mobility is increased to provide site relaxation before the surface is buried by the deposit from the next laser pulse. At higher substrate temperatures the film reactivity with contaminating background gases is expected to increase so that higher substrate temperatures would require lower background gas pressures.

Mechanism of composition change in sputter deposition of barium ferrite films with sputtering gas pressure

E. Suzuki and Y. Hoshi^{a)}

In this study, we used computer simulation to investigate changes in the composition of hexagonal barium ferrite films with sputtering gas pressure obtained by the sputter-deposition processes. The iron content in the film deposited by facing target sputtering increased as the sputtering gas pressure increased and reached a maximum value at a certain gas pressure. These changes in the film composition were explained as follows: sputtered particles scatter when they collide with sputtering gas atoms, and this scattering changes the ratio of the particles reaching the substrate. When the substrate was located to the side of the target, as in a facing target sputtering system, this scattering resulted in an increase in the amount of sputtered particles arriving at the substrate, although too much scattering caused the amount to decrease. When a magnetron sputtering system is used for the film preparation, this gas scattering leads to a decrease in the amount of sputtered particles arriving at the substrate which is located opposite the target. Since this gas scattering depends significantly on the atomic mass of the sputtered particles, the gas pressure dependence of the amount of iron atoms arriving differs considerably from that of the amount of barium atoms arriving. This difference leads to the changes in film composition. © 1998 American Institute of Physics. [S0021-8979(98)46311-4]

I. INTRODUCTION

A hexagonal barium ferrite (BaM) thin film with excellent magnetic properties cannot be obtained unless the film composition is controlled precisely.¹ In the sputter deposition of barium ferrite films, however, the film composition changed significantly when the deposition conditions change,² mainly because high-energy particles, produced from negative oxygen ions emitted from the target, bombarding the film surface caused the composition of the film to differ from that of the target material.^{1,2} This high-energy particle bombardment of the film surface was eliminated in facing target sputtering (FTS), which resulted in only a small change in film composition.¹

The iron content in a BaM film deposited by a FTS system, however, increases with an increase in sputtering gas pressure, reaches a maximum at a certain gas pressure, and decreases with further increases in the gas pressure. To explain these changes in the film composition with sputtering gas pressure, we carried out a computer simulation of the sputter deposition processes and found that changes in the film composition with sputtering gas pressure were mainly caused by the scattering that occurs when sputtered particles in the space between the target and substrate collide with the atoms of the sputtering gas.

In this article, we will show the mechanisms of the composition changes caused by the scattering of sputtered particles through the collisions with sputtering gas atoms in FTS and in conventional magnetron sputtering.

II. SIMULATION OF TRANSPORT PROCESS IN SPUTTERING

A facing target sputtering system and a magnetron sputtering system were assumed to be used for the film deposition (Fig. 1). The trajectory of each of the sputtered particles emitted from the target was calculated and the amount of sputtered particles deposited on the substrate was estimated. This transportation of the sputtered particles was calculated according to the model reported by Motohiro³ and Turner.⁴ The emission angles of sputtered particles from the target

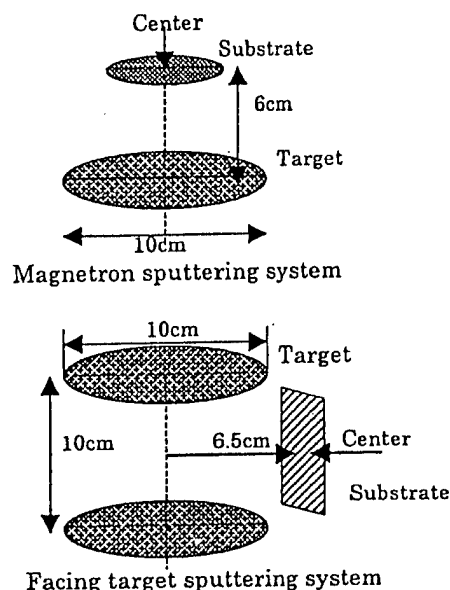

FIG. 1. Target-substrate arrangement in the sputtering systems simulated in this study.

FIG. 2. Relation between sputtering gas pressure and the amounts of iron and barium atoms arriving at the substrate. (a) is obtained for the FTS, and (b) is obtained for the magnetron sputtering system.

were assumed to follow cosine law. The energy distributions of iron atoms emitted from the target were assumed to be emitted from pure metal iron, and calculated by using Thompson's model.⁵ The energy of primary ion which bombards the target surface was assumed to be 780 eV. For barium atoms, the following parameters were used in calculating the energy distribution; atomic number, 56; atomic mass, 137.3; atomic radius, 2.22 Å; length between atoms, 4.35 Å; bonding energy (BaO_2), 8.4 eV in the Thompson's model.⁵ Gas temperature during sputtering was assumed to be 673 K. In the simulation, one million atoms were emitted from the target and the amount of particles incident on the substrate was calculated at various sputtering gas pressures. It should be noted that the sputtering gas, iron, and barium, differ considerably in terms of both atomic radius and atomic mass.

III. RESULTS AND DISCUSSIONS

Figure 2 shows simulated examples of the amount of iron atoms and barium atoms arriving at the substrate in the magnetron sputtering and in the FTS. The amount of atoms arriving in Fig. 2 was normalized by the value obtained with-

FIG. 3. Changes in the arrival ratio of iron atoms to barium atoms with sputtering gas pressure. (a) is obtained for FTS, and (b) is obtained for the magnetron sputtering.

out gas scattering. It should be noted that the amount of atoms arriving in the FTS increases as the sputtering gas pressure increases. On the contrary, the amount of atoms arriving in magnetron sputtering decreases as the sputtering gas pressure increases. This increase in the FTS and decrease in the magnetron sputtering are explained as follows: in a facing target sputtering system, the substrate is located to the side of the target as shown in Fig. 1. In this target-substrate arrangement, scattering of the sputtered particles because of collisions with sputtering gases leads to an increase in the amount of sputtered particles arriving at the substrate. Too much scattering which will occur at a higher gas pressure, however, causing the amount to decrease.

In the magnetron sputtering system, the scattering causes a decrease in the amount of both iron and barium arriving at the substrate as the sputtering gas pressure increases, since the substrate is located opposite the target.

It should also be noted that the gas pressure dependence of the amount of iron atoms arriving at the substrate differs remarkably from that of barium atoms. This is mainly due to the different atomic masses of iron and barium. These differ-

FIG. 4. The amount of iron atoms arriving during sputtering in Ar, Kr, and Xe in FTS.

ences in the amount of deposition particles arriving should cause the film composition to change. The ratio of the amount of the iron atoms to barium atoms arriving at the substrate (arrival ratio) is equivalent to the composition of the deposited film, when the sticking probability is unity. Figure 3 shows the changes in the arrival ratio with sputtering gas pressure in the FTS Fig. 3(a) and in the magnetron sputtering system Fig. 3(b). The arrival ratio of iron to barium estimated from the composition of barium ferrite films deposited by the FTS is also shown in Fig. 3(a). The arrival ratio at 2 mTorr was assumed to be 1. The iron content in the film deposited by FTS increases as the sputtering gas pressure increases, and reaches a maximum at a certain gas pressure. It is clear from the figure that these changes in the arrival ratio obtained from the simulation qualitatively agree with experimental results.

On the other hand, the arrival ratio of iron to barium in the magnetron sputtering system decreases monotonically as the sputtering gas pressure increases, since the amount of arriving iron atoms decreased more steeply than did the amount of barium atoms. This indicates that the iron content in the film should decrease as the sputtering gas pressure

FIG. 5. The amount of barium atoms arriving during sputtering in Ar, Kr, and Xe in FTS.

FIG. 6. Arrival ratio of iron atoms to barium atoms sputtered in Ar, Kr, and Xe in FTS.

increases, if the high-energy particle bombardment of the film surface is eliminated during deposition. However, distinguishing the composition change due to the gas scattering of sputtered atoms was difficult, since the high-energy particle bombardment of the film surface during deposition was not eliminated in this sputtering system.

When other sputtering gases (such as Kr and Xe) are used in place of Ar, the gas pressure dependence of the amount of iron and barium atom arriving will differ significantly from that observed in sputtering using argon gas. This difference will result in changes in the pressure dependence of the film composition. Figures 4 and 5 show examples of the amounts of iron and barium atoms arriving during sputtering in various gases in the FTS. It is clear from the figure that the gas pressure where the amount of atoms arriving takes a maximum value shifts to a lower gas pressure area as the mass of sputtering gas increases. From these results, the changes in film composition with the changes in sputtering gas pressure, shown in Fig. 6, can be derived. The sputtering-gas-dependent changes in film composition should thus be taken into consideration to obtain a film with the desired composition.

IV. CONCLUSIONS

The transportation of sputtered particles from the target to the substrate was investigated. The scattering of sputtered particles by collision with the sputtering gas was found to play an important role in changing the film composition. In addition, it should be noted that this gas scattering effect will lead to a quite different gas pressure dependence of the film composition when the arrangement of target and substrate in the sputtering systems is changed.

Magnetic and structural properties of high coercivity Sm(Co, Ni, Cu) sputtered thin films

C. Prados^{a)} and G. C. Hadjipanayis

Department of Physics and Astronomy, University of Delaware, Newark, Delaware 19716

The effects of heat treatments on the structural and magnetic properties of Sm(Co, Ni, Cu) sputtered thin films were investigated. Crystallization of the initially amorphous magnetic films produces a huge enhancement of coercivity (from 100 Oe to more than 40 kOe). The crystallized structure consists of exchange coupled precipitates in the nanometers range. The pinning of the magnetization reversal at the high anisotropy grains is proposed as the origin of such a magnetic behavior. By tuning the coercivity through the annealing conditions, these systems could be used in a number of applications, from longitudinal recording media to thin film permanent magnet. © 1998 American Institute of Physics. [S0021-8979(98)46411-9]

I. INTRODUCTION

In the last years, SmCo/Cr bilayers films have been proposed as an attractive candidate for ultrahigh density recording media.¹⁻⁴ The main driving force for the use of rare-earth based alloys is to attain a recording density as high as 10–20 Gb/in². In general, modifications of the SmCo₅ composition have been used due to its high coercivity and large magnetic anisotropy. In order to obtain appropriate microstructure and crystallographic orientation in these films, extensive studies have been carried out using different deposition conditions and underlayer materials.⁴

On the other hand, the CaCu₅ type compounds, SmCo_{5-x}Ni_x and SmCo_{5-x}Cu_x are known to exhibit huge values of coercivity due to the so-called giant intrinsic magnetic hardness.^{5,6} In spite of the number of studies related to the properties of the bulks alloys, only a few are reported on thin films. In this article, the structural and magnetic properties of SmCo₅, SmCo₂Cu₃, and SmCo₂Ni₃ thin films deposited by dc magnetron sputtering on a Cr underlayer are studied in the as-deposited state and after subsequent heat treatments. The different microstructures which have been obtained lead to a wide range of coercivity values, which make these compounds suitable for a variety of applications, from longitudinal recording media to thin film permanent magnets.

II. EXPERIMENT

Sm(Co, Ni, Cu)/Cr bilayers were deposited on water cooled Si substrates with a dc magnetron sputtering system. Ar at a pressure of 5 mTorr was used as discharge gas. The Cr underlayers were deposited from a pure (99.9%) solid Cr target. The Sm(Co, Ni, Cu) targets were pressed powder type with nominal compositions SmCo₅, SmCo₂Cu₃, and SmCo₂Ni₃. The deposition rates were 1.25 Å/s for Cr and 6 Å/s for Sm(Co, Ni, Cu) and were calibrated by low angle x-ray diffractometry (XRD). The thickness of the Cr underlayer and the Sm(Co, Ni, Cu) film were 300 and 500 nm, respectively. The role of the Cr underlayer is to promote a

c-axis texture along in plane directions in the Sm–Co film in order to increase its in-plane magnetic anisotropy.⁴ The bilayers were annealed in a vacuum of better than 10⁻⁵ Torr at a constant temperature for 30 min. Different pieces of the same as-deposited sample were submitted to this heat treatment, ranging the annealing temperature for each piece from 400 to 650 °C. Each heat treatment has been labelled with the characteristic annealing temperature. The structural properties were determined by XRD. Room temperature hysteresis loops were measured with a superconducting quantum interference device (SQUID) magnetometer at a maximum applied magnetic field of 55 kOe. Principal remanence curves were measured at room temperature using a vibrating sample magnetometer.

III. RESULTS AND DISCUSSION

The high angle XRD diagrams of the samples showed the (110) peak as the single line from the Cr, and revealed that the Sm(Co, Ni, Cu) layers were amorphous in the as deposited state. After subsequent heat treatments, the amorphous hallow around the position corresponding to the SmCo₅ (111) line started to evolve into a broad nanocrystalline peak with an increasing relative intensity. Figure 1 shows the crystalline grain size for the layers of compositions SmCo₂Cu₃ and SmCo₂Ni₃ as a function of the annealing temperature. Grain size has been determined from the full width at half maximum through the Scherrer's formula. The values are around 20 nm for SmCo₂Ni₃ and 10 nm for SmCo₂Cu₃. The effect of the increasing annealing temperature was to increase the Sm–Co crystallized fraction rather than change the grain size, which slightly grew with the annealing temperature. Preliminary transmission electronic microscopy studies showed that the nanocrystallites are embedded in an amorphous matrix.

Figure 2(a) shows the evolution of coercivity with the annealing temperature for the three compositions. All of them exhibit low coercivity in the as deposited state, because of their amorphous structure, which increases more than two orders of magnitude with the heat treatment. The hardening starts at 515 °C for the case of SmCo₅ and at 450 °C for SmCo₂Ni₃ and SmCo₂Cu₃. The highest value of coercivity

^{a)}Electronic mail: celso@fresno.csic.es

FIG. 1. SmCo_2Cu_3 and SmCo_2Ni_3 grain size as a function of the annealing temperature. Grain size has been determined from the width of the (111) SmCo_5 line using Scherrer's formula.

has been of 42 kOe for the SmCo_2Cu_3 composition, annealed at 550 °C for 30 min (note that coercivity has been determined at room temperature and with a maximum applied field of only 55 kOe). Coercive fields larger than 20 kOe have been obtained for the other two compositions. These values are comparable, and even much larger in the case of SmCo_2Cu_3 , than those reported in epitaxial oriented Sm-Co

FIG. 3. δM plots of the sample with composition SmCo_5 at two representative annealing conditions, 535 (low coercivity) and 550 °C (high coercivity). $\delta M(H)$ has been obtained from the isothermal magnetization curve, $M_r(H)$ and the dc demagnetization $M_d(H)$ through the expression $dM = M_d - (1 - 2M_r)$.

films measured along the hard axis.⁷ Relative remanence (remanent moment divided by the magnetic moment at the maximum applied field) is displayed in Fig. 2(b) for the three compositions at the different annealing temperatures. In the highest coercivity range the relative remanence is around 0.8.

No steps are observed in the measured hysteresis loops over the range of annealing conditions and subsequent structures. This is indicating that, in spite of the different amorphous and crystalline phases present in the films, they behave magnetically coupled. This point is more deeply analyzed through the principal remanence curves.

δM plots have been constructed from the principal remanence curves measured for the three compositions at different annealing conditions (for the definition of the principal remanence curves and δM plots see, for instance, Ref. 8). Figure 3 shows δM plots for the SmCo_5 sample at two representative annealing conditions, 535 °C where the sample still exhibits a low coercivity, and 550 °C in the high coercivity range. The positive values of the δM are interpreted to result from magnetizing interaction between the particles (exchange coupling). The maximum value of the δM plot does not change substantially with the annealing temperature, indicating that the strength of the interaction between particles is independent of the coercivity. Similar behavior is observed in the other two compositions, intergrain interaction is always magnetizing and of the same order for the different crystallization stages.

The structural and magnetic characterization described above provides insight on the outstanding magnetic properties exhibited by these samples. In the as deposited and low temperature annealing stages, the magnetic layers are basically amorphous with low coercivity. A nanocrystalline structure is developed with the higher temperature heat treatments, with the grain size being rather independent of the annealing temperature. The particles are exchange coupled

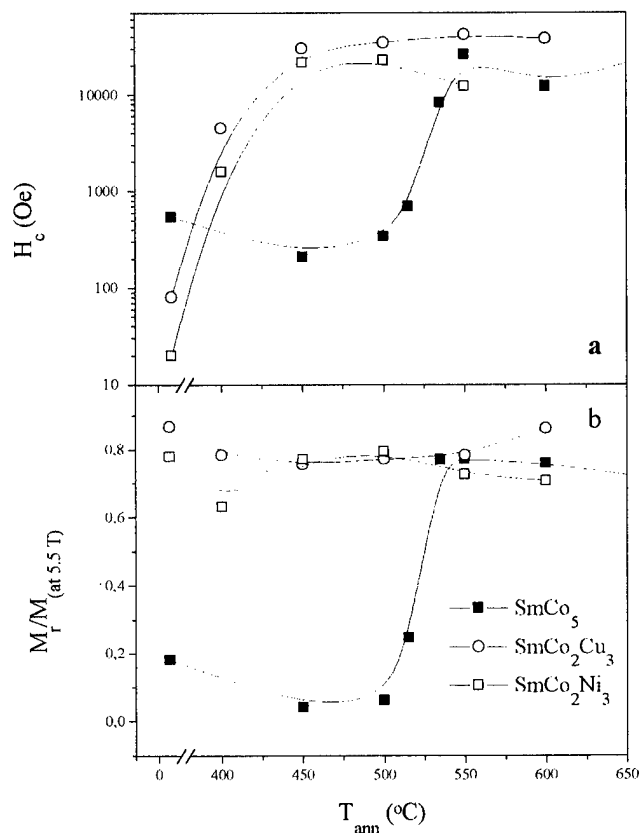

FIG. 2. Evolution of coercivity (a) and relative remanence (b) with the annealing temperature in the films SmCo_2Cu_3 , SmCo_2Ni_3 , and SmCo_5 . Both coercivity and relative remanence have been obtained measuring hysteresis loops with a maximum applied field of 55 kOe.

through the remaining ferromagnetic matrix. The huge enhancement of coercivity may be related to the strong hindrances of the magnetization reversal due to domain wall pinning at the high anisotropy Sm-Co precipitates. The pinning effectiveness improves with the density of crystallites giving rise to such an enhancement of coercivity at annealing temperatures around 500–550 °C.

IV. CONCLUSION

SmCo₅/Cr and giant intrinsic magnetic hardness compounds Sm(Co, Ni, Cu)₅/Cr have been fabricated by dc magnetron sputtering deposition. Heat treatment of the initially amorphous magnetic films results in a refined grain structure with high anisotropy Sm-Co precipitates in the nanometric scale. At the same time, a huge coercivity enhancement (from 100 Oe to 42 kOe in the case of SmCo₂Cu₃) is observed. The nondependence of the strength on the positive magnetic interaction between particles and the average grain size on the crystallization stage, indicated that the coercivity

is related to domain wall pinning at the high anisotropy precipitates. The possibility of tuning the coercivity over a range of more than two orders of magnitude through the annealing conditions, make these films suitable for a variety of applications, from longitudinal recording media to thin film permanent magnets.

Nanocomposites, consisting of a hard magnetic rare earth-transition metal phase exchange coupled to soft magnetic α -Fe or α -(Fe,Co), exhibit enhancement of the remanent magnetization due to exchange coupling across interfaces between grains. Modeling studies have shown that crystallite sizes of less than 20 nm are generally required for significant remanence enhancement and values of remanent magnetization equal to 70%–80% of saturation magnetization have been reported in mechanically alloyed two phase mixtures of α -Fe and a hard magnetic phase, such as $\text{Nd}_2\text{Fe}_{14}\text{B}$. Studies of microstructural evolution during mechanical alloying have shown that as-milled structures consist of a magnetically soft two phase mixture of α -Fe and an amorphous phase. Similar microstructures are observed regardless of whether mechanical milling or mechanical alloying has been carried out. Heat treatment above a critical temperature is required to crystallize grains of the hard magnetic phase. The formation of metastable intermediate phases with interesting magnetic properties may precede formation of the equilibrium phase. It is found that the crystallization temperature is an important parameter determining the grain size of the soft magnetic phase and, hence, magnetic properties. Recent measurements of the reversible and irreversible magnetization behavior of this novel class of permanent magnet are also discussed. © 1998 American Institute of Physics. [S0021-8979(98)42911-6]

I. INTRODUCTION

Nanocomposite permanent magnetic materials have attracted considerable interest since 1991, when it was recognized¹ that exchange coupled, nanoscale mixtures of a hard magnetic phase such as $\text{Nd}_2\text{Fe}_{14}\text{B}$ and a soft magnetic phase such as α -Fe could potentially provide maximum energy products, $(BH)_{\text{max}}$, in excess of 200 kJ/m³.² In addition to the high values of $(BH)_{\text{max}}$ that may be achieved, nanocomposite magnets are of commercial interest because the costly magnetic alignment step is not required to obtain maximum performance and the alloys require less of the expensive rare earth element.

Remanence enhancement is associated with exchange coupling at interfaces separating nanocrystalline hard and soft magnetic phases, which causes the magnetization vector of the soft phase to be rotated toward that of the hard phase, thus increasing the remanent magnetization in the direction of initial magnetization. As a consequence, the material, although crystallographically isotropic, can exhibit remanence values significantly higher than the isotropic value of 0.5 of the saturation magnetization, M_s , for a material with

uniaxial magnetocrystalline anisotropy, without the necessity of crystallographic alignment.

The basic concepts of exchange coupling and remanence enhancement date back to the studies of Meiklejohn and Bean.³ McCallum, *et al.*⁴ first reported remanence enhancement in single phase nanocrystalline melt spun $\text{Nd}_2\text{Fe}_{14}\text{B}$ containing small amounts of Si and Al. The phenomenon was attributed to exchange coupling between ~ 20 nm $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains. Remanence enhancement in nanocrystalline composites of magnetically hard and soft phases was first reported by Coehoorn and co-workers.^{5,6} Remanence values of up to $0.8 M_s$ were measured in a melt-spun $\text{Nd}_4\text{Fe}_{78}\text{B}_{18}$ alloy consisting of $\text{Nd}_2\text{Fe}_{14}\text{B}$, Fe_3B , and α -Fe. Ding *et al.*^{7,8} first reported remanence enhancement in mechanically alloyed two phase α -Fe/ $\text{Sm}_2\text{Fe}_{17}\text{N}_{2.6}$ alloys containing 5–11 at % Sm. The as-milled structures consisted of two phase mixtures of α -Fe and an amorphous phase. Crystallization at temperatures above 773 K resulted in two phase α -Fe/ $\text{Sm}_2\text{Fe}_{17}$ mixtures which were subsequently nitrided at 673 K to form α -Fe/ $\text{Sm}_2\text{Fe}_{17}\text{N}_{2.6}$. The crystallite size was ~ 15 –20 nm in samples heat treated at 873 K. Remanence enhancement has now been observed in a number of mechanically alloyed and heat treated nanocomposite alloys.

^{a)}Electronic mail: pgm@mech.uwa.edu.au

Micromagnetic modeling studies have shown that the magnetic properties of nanocomposite magnets depend strongly on both the microstructure developed during processing and the intrinsic magnetic properties of the individual phases.⁹⁻¹² Of particular importance, the grain size of the soft phase should be less than the exchange length of the soft magnetic phase.¹¹ The calculations of Fischer *et al.*¹¹ predict that M_r should increase logarithmically with increasing grain size and that the magnetic properties are degraded by a nonuniform microstructure. The values of M_r , H_c and $(BH)_{\max}$ predicted by modeling studies exceed experimental values and it is clear that greater attention needs to be placed on the development of optimum microstructures and phase constitutions during processing to enable property improvements to be realized. In this article recent studies of microstructure-property relationships in mechanically alloyed and heat treated rare-earth nanocomposite magnetic materials are reviewed.

II. STRUCTURAL EVOLUTION DURING MECHANICAL ALLOYING

Mechanical alloying and the related processes of mechanical milling and mechanochemical processing have been applied to the synthesis of a wide range of amorphous and nanocrystalline materials.¹³ The application of mechanical alloying to the synthesis of magnetic materials was first reported by Schultz and co-workers in 1987¹⁴ and subsequently has been applied to a wide range of rare-earth permanent magnet alloys.¹⁵

The metastable nanocrystalline and/or amorphous structures which are inherently obtained in mechanically alloyed powder are developed from the repeated processes of deformation and fracture which accompany ball/powder collision events. Plastic deformation of the powder particles initially occurs by the development of shear bands. When sufficiently high dislocation densities are reached the shear bands decompose into sub-grains separated by low-angle grain boundaries. With further milling the sub-grain size is reduced and the sub-grains become randomly oriented and separated by high angle boundaries. The large surface energy of the nanocrystalline grains has been shown to provide the driving force for a crystalline→amorphous phase transition.¹⁶ The rate of diffusion is also important as the diffusion coefficients may be increased by the deformation induced defect density and high local collision temperatures. In many systems the final structure reflects the competition between deformation induced disorder and diffusion limited recovery processes and is independent of whether the starting material is pre-alloyed or a mixture of elemental powders.

The as-milled structures of a wide range of rare-earth permanent magnet alloys are characterized by nanoscale mixtures of crystalline and amorphous phases.¹⁵ For example, both mechanically alloyed and mechanically milled FeNdB alloys consist of a mixture of nanocrystalline α -Fe and amorphous NdFe phases.^{14,17} Mechanical milling of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase has been shown to result in disproportionation into a mixture of α -Fe and amorphous NdFe.¹⁷ The same final phases are formed regardless of whether the starting material has been pre-alloyed.^{17,18}

FIG. 1. Phase changes during mechanical milling of $\text{Nd}_2\text{Fe}_{14}\text{B}$ (Ref. 19).

Microstructure evolution in single phase $\text{Nd}_2\text{Fe}_{14}\text{B}$ and two phase α -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$ composites during mechanical milling has been studied in detail using x-ray diffraction, Mössbauer spectroscopy, and transmission electron microscopy (TEM) measurements.¹⁹ Figure 1 shows the effect of milling time on the volume fraction of the phases present in initially single phase $\text{Nd}_2\text{Fe}_{14}\text{B}$. The phase compositions were determined from Mössbauer measurements.¹⁹ In the early stage of milling, the fraction of the amorphous phase increased rapidly at the expense of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase. After milling for 12 h the microstructure consisted of ~80% amorphous phase and ~20% $\text{Nd}_2\text{Fe}_{14}\text{B}$. For longer milling times the α -Fe phase began to form, while the fraction of amorphous phase remained approximately constant. For milling times exceeding 40 h the fraction of α -Fe reached a constant value of nearly 0.20. A small fraction of $\text{Nd}_2\text{Fe}_{14}\text{B}$ was still present after milling for 80 h. Miao and co-workers¹⁹ suggested that the α -Fe phase forms from the amorphous phase, thus giving a two-stage reaction $\text{Nd}_2\text{Fe}_{14}\text{B} \rightarrow a1 \rightarrow \alpha\text{-Fe} + a2$, where $a1$ and $a2$ refer to the two amorphous phases. A similar two-stage process has also been observed in two phase α -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$ composites.²⁰

In Sm-Co alloys a single amorphous phase is formed during mechanical alloying.^{21,22} The partial substitution of Fe for Co leads to a mixture of a Sm-Co-Fe amorphous phase and nanocrystalline α -(Fe-Co) in milled samples.²³ As shown in Fig. 2, the formation of α -(Fe-Co) was observed when the Fe content exceeded the Sm concentration. A bright field TEM image and selected area diffraction pattern of an as-milled $\text{Sm}_{9.2}\text{Co}_{49.8}\text{Fe}_{40}$ particle are shown in Fig. 3. The distinct diffraction rings are associated with the α -(Fe-Co) phase. The broad diffuse rings which are also evident are consistent with the presence of an amorphous Sm-Co-Fe phase.

III. EFFECT OF HEAT TREATMENT

In all rare earth-transition metal magnetic alloys studied to date the as-milled structure is magnetically soft and a post-milling heat treatment must be carried out to form the

FIG. 2. X-ray diffraction patterns showing effect of Fe content, x , on the phases present in as-milled $\text{Sm}_{10.5}\text{Co}_{89.5-x}\text{Fe}_x$ (Ref. 33).

hard magnetic phase and thus obtain hard magnetic properties. The crystallization temperature in NdFeB alloys has been shown to be a function of the Fe content, increasing from 550 °C to over 600 °C as the equilibrium volume fraction of α -Fe increased from 15% to 75%.²⁰ A two stage crystallization process has been observed to occur in both NdFeB (Ref. 18) and SmCoFe alloys.^{23,24} With NdFeB alloys the first stage involves the crystallization of the amorphous phase with no change in the volume fraction of α -Fe as shown in Fig. 4. No solid state reaction occurred between the amorphous and α -Fe phases during the first stage of crys-

FIG. 4. Phase changes accompanying crystallization in $\text{Nd}_{10}\text{Fe}_{84}\text{B}_6$ (Ref. 18).

tallization. At higher temperatures a decrease in the fraction of α -Fe accompanied further crystallization of $\text{Nd}_2\text{Fe}_{14}\text{B}$. The temperatures required for complete crystallization of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase are sufficiently high for grain growth of the α -Fe phase to occur. Minimum grain sizes of 20 nm have been reported for crystallized α -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$ nanocomposite structures, as compared to 5–10 nm in the as-milled powders.²⁰

Similar observations have been reported for SmFeCo alloys.^{21–24} On annealing, the amorphous phase formed during milling initially crystallized to a metastable intermetallic phase or a mixture of intermetallics having the same composition as the amorphous phase. As with α -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$, no solid state reaction occurred between the amorphous phase and the nanocrystalline α -(Fe-Co) phase during crystallization. The initial crystallization reaction occurred between 430 and 530 °C, with the crystallization temperature decreasing with increasing Sm and Fe content of the amorphous phase. A solid state reaction occurs at higher temperatures between the initially crystallized phase and α -(Fe-Co) to form the equilibrium 2–17 phase. It has been found that the intermetallic phase initially crystallized in $\text{Sm}_{10.5}\text{Co}_{49.5}\text{Fe}_{40}[\text{Sm}(\text{Co},\text{Fe})_7]$ has better magnetic properties than formed by solid state reaction at higher temperatures. Since the structure of the initial intermetallic phase is determined by the composition of the amorphous phase, it is clear that control of the as-milled structure is vital for producing a particular combination of soft and hard phases.

IV. MAGNETIC PROPERTIES OF NANOCOMPOSITE MAGNETS

The magnetic properties of nanocomposite magnets characteristically exhibit high values of remanent magnetization and reversible susceptibility. Figure 5 compares the magnetization curves and recoil loops for mechanically alloyed single phase $\text{Sm}_2\text{Fe}_{14}\text{Ga}_3\text{C}_2$ and exchange coupled $\text{Sm}_2\text{Fe}_{14}\text{Ga}_3\text{C}_2 + 40\%$ α -Fe samples, respectively.²⁵ As shown in Fig. 5, the single phase material exhibits a remanent magnetization equal to $0.5 M_s$ and relatively flat recoil loops associated with a low reversible component of the total

FIG. 3. TEM micrograph of as-milled $\text{Sm}_{9.1}\text{Co}_{49.8}\text{Fe}_{40}$ particle (Ref. 22).

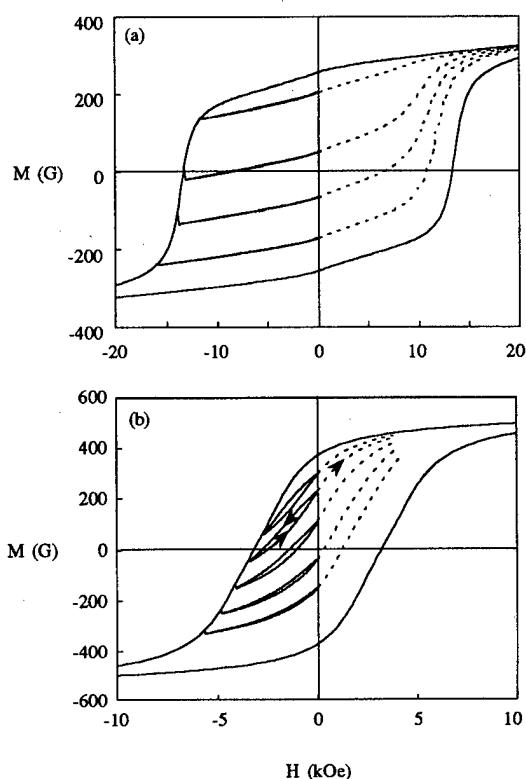

FIG. 5. Magnetization curves and recoil loops for: (a) single phase $\text{Sm}_2\text{Fe}_{14}\text{Ga}_3\text{C}_2$ and (b) $\alpha\text{-Fe}/\text{Sm}_2\text{Fe}_{14}\text{Ga}_3\text{C}_2$ nanocomposite (Ref. 25).

magnetization. In comparison, the two phase material exhibits a higher remanent magnetization ($M_r \sim 0.65 M_s$) and a lower coercivity. The recoil curves exhibit large reversible magnetization.

The high reversible magnetization of exchange coupled nanocomposites is associated with the rotation of the magnetic moments within soft phase grains towards the direction of easy magnetization in neighboring hard grains to which they are exchange coupled. It is important to note that the reversible magnetization changes in the two phase material occur at fields significantly higher than the coercivity of the uncoupled soft phase. This behavior is a clear indication of exchange coupling between nanosized grains of hard and soft phases. Without such exchange coupling irreversible magnetization reversal of the soft phase ($\alpha\text{-Fe}$) would occur at fields of a few Oe, resulting in a reduced remanence and a step in the magnetization curve. The reversible magnetization of the two phase sample is associated almost entirely with the soft phase. Feutrill, McCormick and Street²⁵ have shown that the reversible magnetization in the nanocomposite is limited by the onset of reversal of the hard phase. It is also noted in Fig. 5 that the irreversible relaxation observed at the start of the recoil loops (magnetic viscosity) is significantly reduced in the two phase material as compared with the single phase material. It has been shown that the time dependent magnetic viscosity behavior in exchange coupled magnets is associated with time dependent reversal of the hard phase.²⁵

The nature of the interface between the hard and soft phases in exchange coupled nanocomposites is not well understood. Kneller and Hawig¹ determined that crystallo-

graphic coherence across the interface between hard and soft phases was a necessary condition for exchange coupling and hence remanence enhancement. High resolution TEM studies on nanostructured materials indicate that, while the interfaces take on low energy, highly ordered configurations, there is no crystallographic coherence across interface boundaries.^{26,27} Exchange coupled behavior has been observed in mechanically milled $\text{Nd}_2\text{Fe}_{14}\text{B}$ which consisted of a nanocomposite mixture of $\text{Nd}_2\text{Fe}_{14}\text{B}$ and an amorphous phase.¹⁹ Similar behavior has also been reported in $\text{Sm}_2\text{Fe}_{17}\text{N}_3$, partially disproportionated by mechanical milling to contain a mixture of an amorphous phase and $\text{Sm}_2\text{Fe}_{17}\text{N}_3$.²⁸

Since crystallographic coherence does not exist between the hard and soft phases in these materials, coherence cannot be a necessary condition for exchange coupling and remanence enhancement in nanocomposite magnets. Indeed, significant remanence enhancement has been reported in the melt-spun $\text{Nd}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$ system containing an amorphous intergranular phase.²⁹ Exchange effects between metallic hard and soft magnetic phase components rely on the distributed nature of the electrons involved in cooperative behavior. The range of interaction of collective electrons is of the order of a few interatomic distances. In these circumstances exchange coupling between grains is not critically dependent on crystallographic coherence.

V. FACTORS LIMITING MAGNETIC PROPERTIES

The main factors limiting the performance of mechanically alloyed nanocomposite magnets are microstructure related. The values of a maximum energy product obtained to date are limited by low coercivity, and it is clear that increasing H_c will rely on optimizing the microstructure. In particular, the average grain size and grain size distribution are important parameters determining the magnetic properties. The values of M_r , M_r/M_s , and H_c all decrease with increasing grain size. A number of studies have now shown that the grain size in mechanically alloyed and heat treated nanocomposites exhibiting optimum magnetic properties is typically ~ 20 nm, which is larger than the optimum grain size of ~ 10 nm predicted by modeling studies.^{1,2,9}

As discussed previously, the minimum grain size that can be achieved in mechanically alloyed nanocomposites is limited by the heat treatment conditions employed in the crystallization of the hard magnetic phase. Figures 6 and 7 illustrate the effect of heat treatment time on grain growth and magnetic properties in mechanically alloyed $\text{Sm}_{10.5}\text{Co}_{49.5}\text{Fe}_{40}$ during crystallization at 600°C .^{23,24} The dark field micrographs shown in Fig. 6 were obtained by positioning the objective aperture on the strongest diffraction ring for $\alpha\text{-(Fe-Co)}$. The diffracting grains are thus mainly $\alpha\text{-(Fe-Co)}$, although some bright $\text{Sm}_2(\text{Fe,Co})_7$ grains are also present in the image due to the proximity of the (119) diffraction ring for the 2:7 phase with the (110) diffraction ring of $\alpha\text{-(Fe-Co)}$. In the sample heat treated for 60 min [Fig. 6(b)] the largest grains were identified by energy dispersive spectra (EDS) to be $\alpha\text{-(Fe-Co)}$. Figure 7 shows the decrease in coercivity and M_r/M_s with increasing crystalli-

FIG. 6. Dark field TEM micrographs of mechanically alloyed $\text{Sm}_{10.5}\text{Co}_{49.5}\text{Fe}_{40}$ sample heat treated at 600°C for: (a) 10 min, (b) 60 min (Ref. 23).

zation time. As would be expected, the theoretical density values of $(BH)_{\text{max}}$ decreased significantly with increasing time, from 129 kJ/m^3 for samples crystallized for 5 min to 77 kJ/m^3 for 150 min.²⁴

In $\text{Nd}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$ and SmFeCo nanocomposites crystallization occurs at temperatures of $550\text{--}600^\circ\text{C}$ and $430\text{--}530^\circ\text{C}$, respectively, and grain growth of the soft phase occurs during crystallization. It is clear that to achieve smaller grain sizes it is necessary to reduce grain growth of the soft phase during crystallization. In alloys where a solid state reaction between the amorphous and nanocrystalline phases is required for crystallization of the hard phase, some grain growth of the soft phase is inevitable. Attempts to reduce grain growth of the soft phase through the addition of grain growth inhibitors such as Si, Ta, and Nb have met with mixed success.^{30,31}

The effect of volume fraction of the soft phase in mechanically alloyed nanocomposites has been studied in the $\text{Nd}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$, $\text{Sm}_2\text{Fe}_{17}\text{C}_3/\alpha\text{-Fe}$, and SmFeCo

FIG. 7. Effect of crystallization time on coercivity and reduced remanence in $\text{Sm}_{10.5}\text{Co}_{49.5}\text{Fe}_{40}$ heat treated at 600°C (Ref. 23).

systems.^{8,20,22,32,33} Increasing the fraction of the soft phase increases the remanence but decreases the coercivity, consistent with the results of modeling studies.⁹

The uniformity of the microstructure, in particular the distribution of hard and soft grains and the grain size distribution, is also important in determining magnetic properties. If clusters of soft grains are present, exchange coupling will be diminished even if the grain size is small. As a consequence, nonuniform microstructures cause a decrease in both remanence and coercivity.¹¹ The higher values of M_r and H_c observed in mechanically milled $\text{Nd}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$ nanocomposites, as compared to mechanically alloyed powders of the same nominal composition, have been attributed to the finer and more uniform microstructures obtained in the mechanically milled samples.¹⁸ The clustering of $\alpha\text{-Fe}$ grains in hot pressed $\text{Nd}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$ nanocomposites has also been reported.³¹

A further factor limiting the performance of mechanically alloyed nanocomposite magnets is the difficulty of achieving high densities after consolidation. The magnetic properties reported in most studies to date are calculated from experimental measurements assuming samples are 100% dense. Mechanically alloyed powders exhibit low as-pressed densities in comparison to melt spun materials. The as-pressed density of mechanically alloyed powders is generally limited to about 50% of the theoretical density due to the irregular surface morphology of the particles. Density increases up to $\sim 70\%$ may be achieved during heat treatment. However, higher densities can only be obtained by sintering at higher temperatures, resulting in significant grain growth and a loss of exchange coupled behavior. Alternatively, high densities may be achieved by hot pressing with minimal grain coarsening, provided closely controlled processing conditions are used.³¹

VI. CONCLUSIONS

Mechanical alloying has been shown to be a promising method for the production of nanocomposite magnets. The nanocrystalline grain structure inherently developed by milling and heat treatment is essential for effective exchange coupling and remanence enhancement, enabling high values

of $(BH)_{\max}$ to be obtained. Heat treatment of the as-milled structure is required to form hard magnetic phases. The formation of novel metastable hard phases during heat treatment may provide the basis of new nanocomposite phase mixtures with improved magnetic properties. Recent studies have shown that grain growth accompanying crystallization of the hard magnetic phase and the formation of nonuniform grain structures are important factors which currently limit the magnetic properties of mechanically alloyed nanocomposites.

Micromagnetic simulation of magnetizability of nanocomposite Nd-Fe-B magnets

Thomas Schrefl^{a)} and Josef Fidler

Institute of Applied and Technical Physics, Vienna University of Technology, Wiedner Hauptstrasse 8-10, A-1040 Vienna, Austria

Micromagnetic finite element calculations clearly show that the magnetizability of nanocomposite $\text{Nd}_2\text{Fe}_{14}\text{B}$ magnets improves with increasing α -Fe content. The magnetization curves show a steep increase at the domain propagation field in dc demagnetized samples. Thermally demagnetized states store a higher amount of exchange energy, leading to an increase of the initial susceptibility. An applied field of 960 kA/m leads to a saturation of 85% for a two-phase α -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$ magnet, whereas the $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ magnet and the single-phase $\text{Nd}_2\text{Fe}_{14}\text{B}$ magnets reach a saturation of only 70% and 50%, respectively. The improved saturation behavior of two-phase α -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$ magnets has to be attributed to the exchange field which is provided by α -Fe grains that are already oriented parallel to the field direction. Hard magnetic grains that remain oppositely magnetized after applying the maximum magnetizing field deteriorate the coercive squareness in single-phase $\text{Nd}_2\text{Fe}_{14}\text{B}$ magnets and two-phase $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ magnets. © 1998 American Institute of Physics. [S0021-8979(98)30711-2]

I. INTRODUCTION

Exchange-spring permanent magnets have become a topic of recent research in permanent magnets.¹⁻⁴ A mixture of a magnetically hard and soft phases reduces the overall rare-earth content, while preserving good hard magnetic properties.^{5,6} In addition to the cost reduction, the improved magnetizability of nanocomposite $\text{Nd}_2\text{Fe}_{14}\text{B}$ magnets is a major advantage as compared to conventional bonded magnets.⁷ Panchanathan⁸ compared the saturation behavior of single phase $\text{Nd}_2\text{Fe}_{14}\text{B}$, two phase $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$, and two-phase α -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$ magnets. The magnetization field of 800–960 kA/m leads to a saturation of 55%–60% for a standard, single phase $\text{Nd}_2\text{Fe}_{14}\text{B}$ powder. The α -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$ composites show a saturation of about 80% with a field of only 960 kA/m, while the corresponding bonded magnet reaches a coercive field of 320 kA/m. Rave and co-workers⁹ investigated the effect of different initial states on the initial magnetization curve of nanocrystalline permanent magnets. They reported a higher susceptibility in thermally demagnetized samples than in dc demagnetized samples. This susceptibility difference was qualitatively reproduced by two-dimensional micromagnetic simulations assuming a brick wall model to represent the grain structure.

This work presents three-dimensional micromagnetic calculations of magnetizability and coercivity of α -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$ and $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ two-phase magnets. The magnetic properties of single phase $\text{Nd}_2\text{Fe}_{14}\text{B}$ magnets are calculated as reference. The use of the finite element method allows modeling of realistic microstructures.

II. MICROMAGNETIC SIMULATION OF DEMAGNETIZED STATES

The theoretical description of magnetization processes in ferromagnetic materials starts from the total magnetic Gibbs

free energy. Its minimization provides a stable equilibrium state of a ferromagnetic structure. The actual path of the magnetization towards a local minimum can be computed by the time integration of the Gilbert equation of motion. The transient states show how reversed domains nucleate and propagate.¹⁰ In order to reduce the required computation time, a conjugate gradient method is used to minimize the energy in the present study. Details of the finite element algorithm are described Ref. 6. The cubic model magnet with an edge length of 80 nm consists of 125 polyhedral grains generated from grain growth simulation using Voronoi cells. The average grain diameter is 20 nm. The different phases and the anisotropy directions are randomly assigned to the grains. The composite magnet contains 40 vol % $\text{Nd}_2\text{Fe}_{14}\text{B}$ and either α -Fe or Fe_3B as soft magnetic phase. Table I gives the intrinsic material parameters¹¹⁻¹³ used for the calculations.

The magnetization distribution with the lowest energy represents a thermally demagnetized state. The magnetocrystalline anisotropy energy is the dominating energy term in $\text{Nd}_2\text{Fe}_{14}\text{B}$ magnets. To minimize the energy, the magnetization within the hard magnetic grains must be parallel to the anisotropy directions. The requirement to minimize the magnetostatic energy determines the orientation of the magnetization along the easy axes. Thus, an approximation of a thermally demagnetized state can be obtained from simulated annealing¹⁴ to minimize the magnetostatic energy followed by the calculation of equilibrium states for increasing exchange constant. Indeed the total energy of the thermally demagnetized state calculated by the above procedure is about 5% smaller than the total energy of an equilibrium state with grains initialized randomly along their easy axes. This procedure to calculate the thermally demagnetized state adopts the zero exchange formulation of micromagnetics as outlined by DeSimone.¹⁵ The minimization of the total energy leads to a dc demagnetized state assuming an initial

magnetization antiparallel to each other in two halves of the cube. The net magnetization of the calculated demagnetized states is not exactly zero, owing to the limited number of grains.

III. RESULTS AND DISCUSSION

Figure 1 compares the magnetization curves starting from the thermally demagnetized and dc demagnetized states. The solid, dotted, and dashed lines refer to the α -Fe/Nd₂Fe₁₄B, the Fe₃B/Nd₂Fe₁₄B, and the single-phase Nd₂Fe₁₄B magnets. The magnetization curve of the dc demagnetized Nd₂Fe₁₄B magnet clearly shows three different regimes. At low external fields the magnetization rotates reversibly towards the direction of the applied field within the grains originally magnetized oblique to the field direction. At an external field of about 1000 kA/m the region with upward magnetization starts to expand through the entire magnet leading to a steep increase of the dc magnetization curve at 1340 kA/m. At external fields greater than 1400 kA/m the upward magnetization has completely swept through the magnet, and reversible rotations are the only process to increase the magnetization. The thermally demagnetized state stores a higher amount of exchange energy than the dc demagnetized state, which can be released upon saturation. Only a small external field is required to initiate the irreversible switching of entire grains in the thermally demagnetized Nd₂Fe₁₄B magnet, leading to a higher initial susceptibility.

The soft magnetic grains of the two-phase α -Fe/Nd₂Fe₁₄B or Fe₃B/Nd₂Fe₁₄B magnet become oriented parallel to the field direction at low applied fields. Their exchange field helps to reverse neighboring hard magnetic grains. The comparison of the dc magnetization curves of Fig. 1 shows that the external field required to expand the upward domain through the hard magnetic grains decreases to 750 kA/m as 60% of the hard magnetic phase is replaced by Fe₃B, and to 540 kA/m as Fe₃B is substituted by α -Fe. Figure 2 shows the magnetization process of a two-phase α -Fe/Nd₂Fe₁₄B magnet starting from a dc demagnetized state. The plane where the magnetization component parallel to the field direction becomes zero indicates the position of the domain wall. The solid line denotes the trace of this plane on the surface of the cubic magnet. In nanocrystalline permanent magnets the competitive effects of magnetocrystalline anisotropy and intergrain exchange interactions lead to a strongly inhomogeneous magnetization distribution.⁶ Whereas the magnetization remains parallel to the easy axes in the center of the grains, it deviates from the local easy axis in the vicinity of the grain boundaries. As a consequence, the two regions originally oppositely magnetized are not sepa-

FIG. 1. Calculated magnetization curves starting from a dc-demagnetized state (top) and a thermally demagnetized state (bottom). The solid, dotted, and dashed lines refer to the α -Fe/Nd₂Fe₁₄B, the Fe₃B/Nd₂Fe₁₄B and the single-phase Nd₂Fe₁₄B magnet, respectively. The circles indicate the magnetic states plotted in Fig. 3.

rated by a well-defined domain wall. On both sides of the border between the oppositely magnetized regions, the direction of the magnetization varies on a length scale comparable with the domain wall width. Thus the transition structure is far more complex than in a classical Bloch wall, where the magnetization changes only in the direction perpendicular to the wall. The plot on the left-hand side of Fig. 2 gives the position of the wall for zero applied field. As the external field is increased, the wall bends around Nd₂Fe₁₄B grains following their boundaries. However, the wall may go through α -Fe grains. The plot on the right-hand side of Fig.

FIG. 2. Domain wall propagation in the dc demagnetized α -Fe/Nd₂Fe₁₄B magnet. The solid line gives the trace of the plane where the component of the magnetization parallel to the direction of the applied field becomes zero.

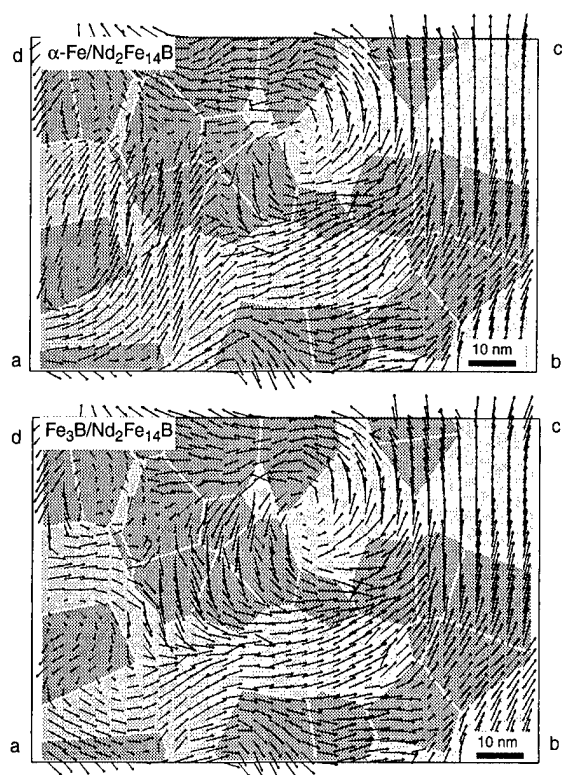

FIG. 3. Magnetization distribution during saturation of the thermally demagnetized α -Fe/Nd₂Fe₁₄B and Fe₃B/Nd₂Fe₁₄B magnet. The magnetization is projected onto a plane parallel to the field direction for an applied field of 390 kA/m. The field is applied parallel to the vector from point b to point c.

2 depicts the trace of the wall for an applied field of 340 kA/m, showing the deflection of the wall around the hard magnetic grains.

The comparison of the magnetization curves of Fig. 1 clearly shows that the magnetizability increases with increasing α -Fe content. In the thermally demagnetized samples, an applied field of 960 kA/m leads to 85% saturation for a two-phase α -Fe/Nd₂Fe₁₄B magnet and to 70% saturation for the Fe₃B/Nd₂Fe₁₄B magnet. For the same applied field, the single phase magnet reaches a saturation of only 50%. The very same mechanism which causes the decrease of the domain propagation field in the dc demagnetized samples with increasing α -Fe content improves the saturation behavior of thermally demagnetized, two-phase magnets. The magnetization of the Fe₃B and α -Fe grains becomes oriented along the saturation direction at an applied field of 400 kA/m. The exchange field provided by the saturated soft magnetic grains facilitates the alignment of neighboring hard magnetic grains. Figure 3 gives the magnetization distribution in a slice plane parallel to the field direction. Fe₃B grains require a larger applied field to become aligned parallel to the field direction than α -Fe grains. Neighboring hard and soft magnet grains already saturated at an applied field of 390 kA/m in the α -Fe/Nd₂Fe₁₄B magnet remain reversed in the Fe₃B/Nd₂Fe₁₄B magnet.

Figure 4 presents the calculated demagnetization curves as a function of the saturation field. Hard magnetic grains

FIG. 4. Influence of the applied field on the loop shape and the coercive field for α -Fe/Nd₂Fe₁₄B and Fe₃B/Nd₂Fe₁₄B magnets. The demagnetization curves were calculated after saturation with an applied field of 800, 960, and 1120 kA/m.

that remain oppositely magnetized deteriorate coercivity and remanence in Fe₃B/Nd₂Fe₁₄B magnets for a saturation field lower than 1000 kA/m. Two phase α -Fe/Nd₂Fe₁₄B magnets show square hysteresis loops. The calculated values for the coercive field and the remanence are 340 kA/m and 1.2 T for a saturation field of 960 kA/m.

Thick $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ nanocomposite permanent magnet flakes prepared by slow quenching

H. Kanekiyo and S. Hirosawa^{a)}

Research and Development Division, Sumitomo Special Metals Co., Ltd., 2-15-17 Egawa, Shimamoto-cho, Mishima-gun, Osaka 618, Japan

Thick permanent magnet flakes of $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ nanocomposites have been prepared directly from molten alloys by means of the low surface-velocity melt-spinning technique under a vacuum. Dependence of microstructure and magnetic properties of $\text{Nd}_4\text{Fe}_{77.5}\text{B}_{18.5}$ rapidly solidified alloys have been studied as functions of pressure of a melt-spinner chamber and the surface velocity of a Cu roll. An as-spun alloy of $\text{Nd}_{3.5}\text{Dy}_1\text{Fe}_{73}\text{Co}_3\text{Ga}_1\text{B}_{18.5}$ obtained at a $V_s = 3.3$ m/s under a 1.3 kPa Ar atmosphere has a thickness of 240 μm and the room temperature magnetic properties of $(BH)_{\text{max}} = 131.6$ kJ/m³, $B_r = 1.15$ T, and $H_{cJ} = 400$ kA/m. © 1998 American Institute of Physics. I. INTRODUCTION

Nanocomposite permanent magnet materials consisting of tetragonal Fe_3B and $\text{Nd}_2\text{Fe}_{14}\text{B}$ have been attracting much interest since they were reported by Coehoorn in 1988.¹ The hard magnetic properties of these alloys have been significantly improved by the present authors by means of modifications of composition,^{2,3} adding a practical importance on these materials as new candidates for hard magnetic ingredients of resin-bonded permanent magnets.

These materials are produced from amorphous alloys prepared by a single-roll melt-spinning technique and a subsequent heat treatment procedure, in which the amorphous alloys crystallize into a nanocomposite composed of the metastable Fe_3B and the hard magnetic $\text{Nd}_2\text{Fe}_{14}\text{B}$ phases with a minor amount of $\alpha\text{-Fe}$.¹

Although it has been known that $\text{Nd}_2\text{Fe}_{14}\text{B}$ melt-spun materials show good hard magnetic properties in the as-spun state,⁴ the effort to obtain the hard magnetic $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ as-spun alloys has been unsuccessful. However, to make a conclusive verdict, the effects of quenching conditions on the rapidly solidified alloys have not been thoroughly investigated in the vicinity of the $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ nanocomposite compositions.

This article reports the effects of melt-spinning conditions, particularly the pressure of the chamber atmosphere of a melt spinner and the surface velocity of a Cu roll during melt spinning, on the microstructure and hard magnetic properties of as-spun alloys. The $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ nanocomposites have been obtained in the as-quenched alloys for the first time by reducing the chamber pressure down to a practically vacuum regime and the roll surface velocity to a range between 3 and 5 m/s. The hard magnetic materials thus obtained are thick flakes. They may be processed either into crushed powder for fabrication of resin-bonded magnets or directly into thin platelet permanent magnets simply by cutting or machining.

II. EXPERIMENTAL PROCEDURES

Alloys of compositions of $\text{Nd}_4\text{Fe}_{77.5}\text{B}_{18.5}$ and $\text{Nd}_{3.5}\text{Dy}_1\text{Fe}_{73}\text{Co}_3\text{Ga}_1\text{B}_{18.5}$ were prepared by the single role melt-spinning technique under an Ar pressure (P) ranging from 1.3 to 95 kPa. About 30 g of alloys were taken from premelted large ingots and remelted in a quartz crucible. Immediately after the temperature of the molten alloys reached approximately 1300 °C, they were injected through an orifice of a diameter of 0.8 mm cut at the bottom of the crucible. The injection pressure was kept to be a constant value of 30 kPa relative to the chamber pressure. The quenching roll was made of Cu and rotated at a surface velocity (V_s) in a range between 2 and 30 m/s.

The rapidly solidified alloys were investigated using differential thermal analysis (DTA) and powder x-ray diffraction (XRD) analysis using the Cu $K\alpha$ radiation. The surfaces of rapidly solidified alloys were investigated by scanning electron microscopy (SEM). Magnetic properties of the materials were measured at room temperature along the widest surface of flake-shaped specimens using a vibrating sample magnetometer (VSM).

III. EXPERIMENTAL RESULTS

When V_s is 5 m/s, which is extremely slow compared to conventional conditions used for Nd-Fe-B melt-spun hard magnets (V_s is typically 20 m/s), rapidly solidified $\text{Nd}_4\text{Fe}_{77.5}\text{B}_{18.5}$ alloys are obtained as crystalline. For a chamber pressure (P) of 75 kPa, the condition used for our previous studies, the existence of $\alpha\text{-Fe}$ in the alloy is readily confirmed by XRD as shown in Fig. 1. This alloy has an intrinsic coercivity of approximately 20 kA/m, which is negligible as a hard magnet. When P is reduced to 1.3 kPa, the $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ composite structure is realized in the as-spun alloy for the same V_s (Fig. 1). The diffraction peaks are relatively broad, indicating that the material consists of nanometer-sized crystallites.

Observations of the surface morphology of the flakes by SEM reveal that the flakes obtained under a chamber pressure close to atmospheric pressure have shallow dimples of

FIG. 1. Comparison of x-ray diffraction patterns of $\text{Nd}_4\text{Fe}_{77.5}\text{B}_{18.5}$ as-spun alloys under different chamber pressures of 75 and 1.3 kPa Ar on a Cu-roll surface moving at $V_s = 5$ m/s.

an approximate diameter of $200\ \mu\text{m}$ on the surface which had contact with the quenching roll ("the roll-side surface" as opposed to the free surface). These are gas pockets created when a strand of the molten alloy had contact with the surface of the quenching roll. On the other hand, the roll-side surfaces are smooth and optically flat when the chamber pressure is lower than 30 kPa. It has been observed that, for these reduced chamber pressures, the quenched alloy is a continuous ribbon or a thin plate.

Figure 2 shows powder XRD patterns of the as-spun $\text{Nd}_4\text{Fe}_{77.5}\text{B}_{18.5}$ alloys for a chamber pressure of 1.3 kPa, showing the effects of V_s on the microstructure. For $V_s = 20$ m/s, an amorphous material is obtained in an agreement with the previous studies. With decreasing V_s , diffraction peaks from Fe_3B and $\text{Nd}_2\text{Fe}_{14}\text{B}$ gradually develop, indicating development of the nanocomposite structure. The dependence of the thickness on V_s of the rapidly solidified

FIG. 2. X-ray diffraction patterns of $\text{Nd}_4\text{Fe}_{77.5}\text{B}_{18.5}$ as-spun alloys obtained under an Ar pressure of 1.3 kPa on a Cu-roll surface moving at different velocities.

FIG. 3. Dependence of thickness on roll surface velocity for $\text{Nd}_4\text{Fe}_{77.5}\text{B}_{18.5}$ as-spun alloys obtained under an Ar pressure of 1.3 kPa. The width of the ribbons are in a range between 0.7 and 1.2 mm.

$\text{Nd}_4\text{Fe}_{77.5}\text{B}_{18.5}$ ribbons obtained with $P = 1.3$ kPa is shown in Fig. 3. Ribbon widths were in the range between 0.7 and 1.2 mm with the inverse dependence on V_s .

The dependence of magnetic properties of the rapidly solidified $\text{Nd}_4\text{Fe}_{77.5}\text{B}_{18.5}$ alloys on V_s is shown in Fig. 4. Except for the magnetization measured under an external field of 1.2 T ($J_{1.2}$), the intrinsic coercivity, remanence (B_r), and maximum energy product [$(BH)_{\text{max}}$] show strong dependencies on V_s . The optimum hard magnetic properties have been obtained with $V_s = 5$ m/s.

Demagnetization curves of rapidly solidified $\text{Nd}_4\text{Fe}_{77.5}\text{B}_{18.5}$ and $\text{Nd}_{3.5}\text{Dy}_1\text{Fe}_{73}\text{Co}_3\text{Ga}_1\text{B}_{18.5}$ alloys are shown in Fig. 5. The optimal V_s value depends on alloy concentration. The optimal V_s for the latter alloy is 3.3 m/s and the thickness is $240\ \mu\text{m}$. The optimal magnetic properties are $(BH)_{\text{max}} = 118.1\ \text{kJ/m}^3$, $H_{\text{cJ}} = 276\ \text{kA/m}$, and $B_r = 1.25\ \text{T}$ for $\text{Nd}_4\text{Fe}_{77.5}\text{B}_{18.5}$ and $(BH)_{\text{max}} = 131.6\ \text{kJ/m}^3$, $H_{\text{cJ}} = 400\ \text{kA/m}$, and $B_r = 1.15\ \text{T}$ for

FIG. 4. Dependence of magnetic properties of $\text{Nd}_4\text{Fe}_{77.5}\text{B}_{18.5}$ as-spun alloys obtained under an Ar pressure of 1.3 kPa on the roll surface velocity, V_s .

FIG. 5. Demagnetization curves of as-spun $\text{Nd}_4\text{Fe}_{77.5}\text{B}_{18.5}$ and $\text{Nd}_{3.5}\text{Dy}_1\text{Fe}_{73}\text{Co}_3\text{Ga}_1\text{B}_{18.5}$ obtained under an 1.3 kPa Ar atmosphere on Cu-roll surface moving at $V_s = 5$ and 3.3 m/s, respectively.

$\text{Nd}_{3.5}\text{Dy}_1\text{Fe}_{73}\text{Co}_3\text{Ga}_1\text{B}_{18.5}$. These values are equivalent to those obtained previously on alloys crystallized from amorphous precursors.² These materials are magnetically isotropic.

IV. DISCUSSION

In this investigation, it has been clearly demonstrated that the chamber pressure during the melt-spinning procedure has a pronounced effect on microstructure and magnetic properties of as-spun alloys of the $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ nanocomposite compositions. The presence of gas pockets observed on the roll-side surface of flakes obtained under a near atmospheric chamber pressure would significantly retard heat flow from the molten alloy to the surface of the quenching roll, causing large differences of cooling rates throughout the alloy flakes during solidification. Without the formation of gas pockets in the near vacuum atmosphere, uniform cooling must have been realized. As a result, an unequivocal dependence of microstructure and magnetic properties of these alloys on V_s has been observed, showing the existence of a window in which as-spun hard magnet materials of the $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ nanocomposite structure can be obtained.

In the Nd-Fe-B system, other types of nanocomposites consisting of α -Fe and $\text{Nd}_2\text{Fe}_{14}\text{B}$ are possible in the Fe-rich composition regime. It has been reported that these nanocomposites are obtainable either directly by a melt-spinning technique or via heat treatment of amorphous precursors,^{5,6} which is not surprising because both α -Fe and $\text{Nd}_2\text{Fe}_{14}\text{B}$ are in equilibrium for compositions of the alloys. In contrast, the $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ nanocomposites are believed to be metastable because they decompose into a stable mixture of α -Fe and $\text{Nd}_{11}\text{Fe}_{14}\text{B}_4$ when annealed at a temperature above approximately 800 °C.⁷ Therefore, the formation of a metastable composite structure in this type of alloy is not trivial. The possibility of Fe_3B being a high temperature equilibrium phase above 1160 °C was pointed out by Kahn *et al.*⁸ Therefore, Fe_3B may have been formed in the alloy at a high

temperature to consume a substantial amount of boron to allow the formation of $\text{Nd}_2\text{Fe}_{14}\text{B}$ at a lower temperature in the boron-depleted, neodymium-rich region of the alloy. In the present investigation, however, the as-quenched microstructure changed gradually from an amorphous to a $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ nanocomposite with decreasing rotor surface velocity in a similar manner as the microstructure of a corresponding amorphous alloy does during successive heat treatments.⁷ This observation may possibly indicate that an amorphous solid is formed first and subsequently decomposed into Fe_3B and $\text{Nd}_2\text{Fe}_{14}\text{B}$ in the temperature range in which these phases are metastable when cooling rate is moderate. The elucidation of the rapid solidification behavior of this type of alloy is left for further investigations.

The $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ hard magnets obtained in relatively slow surface velocities are continuous thick ribbons, the length of which may be as long as a few meters. The limitation of length occurs from a small span of a sample recovery chamber available in the experimental facility. The thickness of the materials is on the order of a few hundred micrometers, for which shaping of most conventional hard magnet materials by machining or polishing is not practical. Although it is known that MnAlC and FeCrCo permanent magnet materials can be fabricated by rolling in their manufacturing process to produce plate-shaped permanent magnets, the former material has a lower saturation magnetization and the latter has only a small coercivity compared to the present materials obtained by direct quenching. Therefore, the thick flake magnets obtained in this investigation are unique and may open new application fields in which thin platelet permanent magnets with a high energy product are desired.

V. CONCLUSION

The $\text{Fe}_3\text{B}/\text{Nd}_2\text{Fe}_{14}\text{B}$ nanocomposite permanent magnets can be obtained directly from the melt via a melt-spinning technique by accomplishing the rapid solidification process under a reduced pressure of 1.3 kPa on a Cu roll moving at a surface velocity significantly slower than conventional melt spinning. Platelet permanent magnets with a thickness of 240 μm and magnetic properties of $(BH)_{\text{max}} = 131.6 \text{ kJ/m}^3$, $H_{\text{cJ}} = 400 \text{ kA/m}$, and $B_r = 1.15 \text{ T}$ have been obtained for $\text{Nd}_{3.5}\text{Dy}_1\text{Fe}_{73}\text{Co}_3\text{Ga}_1\text{B}_{16.5}$.

Analysis of magnetic behavior of exchange-enhanced SmFeCo magnets

M. Dahlgren and R. Grössinger

*Institut für Experimentalphysik, Technische Universität Wien,
Wiedner Hauptstrasse 8-10A-1040 Wien, Austria*

D. R. Cornejo and F. P. Missell

Instituto de Física, Universidade de São Paulo, CP 66318, 05315-970 São Paulo, SP, Brazil

A series of densified exchange-enhanced SmFeCo magnets was produced by mechanical alloying, followed by a heat treatment. The nanocrystalline phases and the grain size distribution of the samples were characterized from x-ray diffraction patterns. Magnetic measurements in terms of different models were analyzed for the temperature behavior of the magnetization and coercivity. One analytical formulation was derived from the random anisotropy model predicting that with increasing M_r/M_s ratio a decreasing coercivity occurs. Another numerical approach, which is based on a micromagnetic calculation using finite element techniques was also applied. Attempts were made to improve the existing model derived from the finite element technique. The nucleation model was found to be unsatisfactory for describing the temperature-dependent coercivity. © 1998 American Institute of Physics. [S0021-8979(98)43011-1]

Nanocrystalline hard magnetic materials increasingly form an important area for research on magnetic materials. This development started with the study of low rare earth containing materials like melt-spun $\text{Nd}_4\text{Fe}_{78}\text{B}_{18}$ by Coehoorn *et al.* in 1988.¹ Independently, in 1987 Keem *et al.* reported a remanence enhancement in isotropic rapidly-quenched Nd-Fe-B ribbons containing additions of Al and Si.^{2,3} Since then many different compounds such as Sm-Co⁴ with a maximum coercivity up to 75 kOe or a two-phase $\alpha\text{-Fe/Sm-Fe-N}^5$ were produced in the nanocrystalline or nanocomposite state.

Stoner and Wohlfarth⁶ predicted that the remanence should be half of the saturation magnetization (M_s) for single phase uniaxial materials assuming an isotropic set of noninteracting grains. From this prediction single-phase uniaxial materials are defined as remanence enhanced when the remanence is above half of M_s . In all these materials nanocrystals of the hard magnetic phase with grain sizes between 10 and 35 nm were found. For hard magnetic materials, the anisotropy energy overrides in general the stray field energy. In this case, the length where the extension of spin inhomogeneities is reduced by $1/e$ is referred to as the exchange length $\ell_{\text{ex}} = \sqrt{A/K}$ (where A is the exchange stiffness constant and K is the anisotropy constant). Due to the fact that the grain size is of the same order as the magnetic exchange length, the coupling between the grains becomes extensive enough to considerably enhance the remanence.

All these materials are isotropic due to the production processes generally used (rapidly quenching, mechanical alloying). It was found that the exchange coupling influences intrinsic properties such as the spin reorientation temperature⁷ as well as the Curie temperature.⁸ A simple measure of the exchange coupling is, in addition to the shape of recoil curves⁹ and the hysteresis loop, the ratio remanence M_r to saturation magnetization M_s .

Starting from elementary powders, three compositions, $\text{Sm}_{18.1}\text{Fe}_{11.0}\text{Co}_{70.9}$, $\text{Sm}_{18.4}\text{Fe}_{23.4}\text{Co}_{58.2}$, and

$\text{Sm}_{18.2}\text{Fe}_{33.2}\text{Co}_{48.6}$, were produced by mechanical alloying resulting in a quasi-amorphous matrix. The quasi-amorphous materials were cold pressed into 3 mm diameter cylinder, wrapped in Ta foil, and heated under 10^{-5} mbar vacuum for 15 min at 600–700 °C. So, the quasi-amorphous Sm-Fe-Co can transform into many different nanophases, such as $\text{Sm}_2(\text{Co, Fe})_{17}$, $\text{Sm}(\text{Co, Fe})_5$, $\text{Sm}_2(\text{Co, Fe})_7$, $\text{Sm}(\text{Co, Fe})_3$, and $\alpha\text{-(Fe, Co)}$. Because the phases have similar crystallographic structure it is very difficult to distinguish the different phases from x-ray diffraction. For the compositions used in the present work, the expected hard magnetic phase would be the $\text{Sm}(\text{Co, Fe})_5$ phase. However, according to a previous study¹⁰ the presence of Fe in the quasi-amorphous phase seems to prevent the formation of $\text{Sm}(\text{Co, Fe})_5$. Instead a mixture $\text{Sm}_2(\text{Co, Fe})_{17}$, $\text{Sm}_2(\text{Co, Fe})_7$, $\text{Sm}(\text{Co, Fe})_3$, and $\alpha\text{-(Fe, Co)}$ was found.¹⁰ From our x-ray measurement it seems that $\text{Sm}_2(\text{Co, Fe})_7$ and $\text{Sm}(\text{Co, Fe})_3$ do not exist in the samples. The average grain size and the grain size distribution of the samples were evaluated by analyzing the x-ray diffraction line broadening (Table I).^{11,12}

The determination of the saturation magnetization, M_s , is very important to obtain the characteristic ratio M_r/M_s for exchange enhanced magnets. To determine M_s of isotropic hard magnetic materials accurately, high fields magnetic measurements are necessary in order to exceed the high magnetocrystalline anisotropy of the hard magnetic phases as well as a reliable extrapolation method (e.g., the law of approach to saturation). Therefore magnetization measurements were performed on the SmFeCo magnets in a pulsed field magnetometer with a maximum applied field of 35 T. With this method the temperature dependence of the ratio M_r/M_s as well as the coercivity were measured from 4.2 K up to room temperature. The anisotropy field was estimated from the law of approach to saturation. The estimated anisotropy field for the samples were determined to be between 20 and 30 T at room temperature. This indicates that $\text{Sm}_2(\text{Co, Fe})_7$ ($H_a \approx 30$ T at room temperature) or

TABLE I. The average grain size, D_v (see Refs. 11, 12) for different compositions evaluated by analyzing the x-ray diffraction line broadening. (Sm, Fe, Co) grain corresponds to the grains composed from the hard magnetic (Sm, Fe, Co) phases.

	Sm _{18.1} Fe _{11.0} Co _{70.9}	Sm _{18.4} Fe _{23.4} Co _{58.2}	Sm _{18.2} Fe _{33.2} Co _{48.6}
(Sm, Fe, Co) grain	11.9 nm	17.5 nm	19 nm

Sm₁(Co, Fe)₅ ($H_a \approx 30$ T at room temperature) is more probable instead of Sm₂(Co, Fe)₁₇ ($H_a \approx 10$ T at room temperature).

In Fig. 1 it is evident that the ratio M_r/M_s is increasing with decreasing temperature. This indicates that the coupling is increasing at lower temperature. If the coupling is increasing we would expect that the exchange length should increase with decreasing temperature. This is possible if the anisotropy constant K is decreasing. Blaettner *et al.*¹³ found this behavior for Sm₂Co₇. Therefore those data were used to describe the anisotropy field.

Using the available data, analytical relations between the coercivity and the enhanced remanence can be tested. There exists¹⁴ one analytical prediction relating coercivity and remanence:

$$\frac{M_r}{M_s} = \frac{1}{2} \left[\cos \left(1 - 2 \frac{H_C}{H_A} \right) + \frac{\pi}{2} \sin \left(1 - 2 \frac{H_C}{H_A} \right) \right]. \quad (1)$$

This formula was derived from the random anisotropy model¹⁵ and predicts a decreasing coercivity with increasing M_r/M_s ratio. This analytical relation was tested for our measurements and could not reproduce the temperature behavior. In fact, the results showed a behavior opposite to the prediction of the model. In our measurements both M_r/M_s and the coercivity are increasing (compare Fig. 1 and Fig. 3).

Another numerical approach, which is based on a micro-magnetic calculation using finite element techniques¹⁶ delivers a relation of the type:

FIG. 1. The temperature behavior of the remanence to saturation magnetization ratio measured using a pulsed field magnetometer. A fit according to the model of Fischer *et al.* (see Ref. 16) is included for comparison.

FIG. 2. The modified model of Fischer *et al.* (see Ref. 16) which assumes the exchange coupling to be three dimensional, is compared to the measured data.

$$\frac{M_r}{M_s} = a + b \ln(D/\delta_B^{\text{hard}}) \quad (2)$$

with $M_s = M_s^{\text{hard}} \nu^{\text{hard}} + M_s^{\text{soft}} \nu^{\text{soft}}$, where D is a grain size, $\delta_B = \pi \sqrt{A/K}$ represent the domain wall width of the hard magnetic phase, M_s^{hard} , M_s^{soft} are the saturation polarization of the hard and soft magnetic phases, and ν^{hard} , ν^{soft} are the volume fractions of the hard and soft magnetic phases. In the case of only uncoupled hard magnetic grains $a=0.5$ and $b=0$, whereas in the other cases a increases with the amount of the soft magnetic phase: $0.5 < a < 1$. b is -0.045 without the soft magnetic phase and may increase to -0.15 depending on the amount of the soft magnetic phase.¹⁶

Since, in all of the samples measured, there existed only a small amount of soft magnetic phase, a was fixed to be 0.5. If the parameter a was left free in the fitting procedure it tended to reach values in the range of 0.1–0.3, which have no physical meaning.

This model shows the right tendency when applying it to the measured data, but the fit was not able to reproduce the actual temperature behavior. One disadvantage of Eq. (2) is

FIG. 3. Temperature dependence of the coercivity measured by using a pulsed field magnetometer.

FIG. 4. The nucleation model (see Ref. 17) applied to the measured data.

that D/δ_B describes the coupling of the phases for a one-dimensional model. A 2D model would be able to describe the ratio of the total grain area to the exchange coupled grain area. If, instead of D/δ_B , the ratio of total volume V_{tot} to coupled volume V_{coupl} is used, a 3D model would result. The ratio of coupled volume to total volume can be defined as the reduced volume V_{red} .

$$V_{\text{red}} \equiv \frac{V_{\text{coupl}}}{V_{\text{tot}}} = \frac{(D/2)^3 - (D/2 - \ell_{\text{ex}})^3}{(D/2)^3}. \quad (3)$$

By introducing the reduced volume, the following expression can be defined:

$$\frac{M_r}{M_s} = a + b \ln(1/V_{\text{red}}). \quad (4)$$

If the sample is fully exchange coupled, M_r/M_s in Eq. (4) should be equal to 1 when V_{red} is equal to 1. For the coupled boundary condition M_r/M_s [$\ln(1)=0$] would be equal to a and with $a=1$ the boundary condition is fulfilled. If the grains in the magnet are uncoupled, M_r/M_s in Eq. (4) should be between 0.5 and 1 (depending on the amount of soft magnetic phase), when b and V_{red} are equal to zero. By applying l'Hospital rule on Eq. (4) and letting b and V_{red} approach zero M_r/M_s will be equal to a . Since a can be chosen between 0.5 and 1 also this boundary condition is fulfilled.

In Fig. 2 the modified model of Eq. (4) is tested and indeed the experimental data fit the model. Increasing the amount of Fe in the samples results in a maximum for the parameter a and a minimum for parameter b for the sample with Fe=23 at%. By comparing the values in Fig. 1 with the values in Fig. 2, b seems to be of a factor 10 larger in the modified model. Also the expected values for b ($-0.045 < b < -0.15$) from Fischer *et al.*,¹⁶ are exceeded by a factor of 2 in the modified model.

We also attempted to fit the coercivity using an equation similar to that for the ratio M_r/M_s from Fischer *et al.*:¹⁶

$$H_C = H_a [c + d \ln(D/\delta_B^{\text{hard}})]. \quad (5)$$

However, this formula shows a different behavior than the measured data. Here H_C/H_a has a convex shape and $\ln(D/\delta_B)$ has a concave shape with the temperature.

The nucleation model¹⁷ can be used to describe $H_C(T)/J_s(T)$:

$$\frac{H_C}{J_s} = \alpha \frac{H_a}{J_x} - N_{\text{eff}}. \quad (6)$$

The values obtained from the nucleation model are shown in Fig. 4.

Here the microstructural α parameter has negative values. A negative value of the α parameter has no physical meaning, which indicates that the nucleation model cannot be applied for our samples. However, it is worth noting that an increase of Fe in the samples results in a decrease of the microstructural parameters. One more disadvantage of the nucleation model is that it only indicates if the magnetization processes is nucleation controlled and do not delivers any deeper understanding of the exchange coupling. The same problems arise when applying a similar model such as the nucleus-expansion model.¹⁸

The effect of boron and rare earth contents on the magnetic properties of La and Cr substituted α -Fe/ R_2 Fe₁₄B-type nanocomposites

W. C. Chang,^{a)} D. Y. Chiou, and S. H. Wu

B. M. Ma, Q. Chen, and C. O. Bounds

Rhodia, Rare Earths and Gallium, CN 7500, Cranbury, New Jersey 08512

The effect of phase transformations on the magnetic properties of rare earth lean ($\text{Nd}_{0.95}\text{La}_{0.05}$)_{9.5}Fe_{82.5-x}Cr₂B_{6+x} ($x=0$ to 4.5) and ($\text{Nd}_{0.95}\text{La}_{0.05}$)_{7.5+y}Fe_{80.5-y}Cr₂B₁₀ ($y=0$ to 4) melt spun ribbons has been investigated. The phase mixture, after optimum thermal processing, was found to be strongly dependent upon the rare earth and boron contents. Two magnetic phases, namely α -Fe and $R_2\text{Fe}_{14}\text{B}$, were found in ($\text{Nd}_{0.95}\text{La}_{0.05}$)_{9.5}Fe_{82.5-x}Cr₂B_{6+x} alloy ribbons with x ranging from 0 to 4.5. For a fixed rare earth content, increases in the boron concentration resulted in a higher volume fraction of the $R_2\text{Fe}_{14}\text{B}$ phase, which led to an increase in the intrinsic coercive force from 7.1 kOe for $x=0$ to 12.6 kOe for $x=4.2$. A $B_r=9.6$ kG, $iH_c=9.5$ kOe, and $(BH)_{\max}=15.5$ MGOe have been obtained in the alloy ribbons with $x=4.5$. On the other hand, the increase in the total rare earth content, or y , was found to suppress the formation of the metastable Fe₃B and/or $R_2\text{Fe}_{23}\text{B}_3$ phases and to yield an α -Fe/ $R_2\text{Fe}_{14}\text{B}$ mixture for $y>1$. This increase in total rare earth content not only increases the volume fraction of both the $R_2\text{Fe}_{14}\text{B}$ and α -Fe phases but also decreases the average grain size of these phases as evidenced by transmission electron microscopy analysis. This decrease in the average grain size may subsequently enhance the intrinsic coercivity and the remanence of the ribbons. A B_r of 9.5 kG, a iH_c of 13.2 kOe, and a $(BH)_{\max}$ of 18 MGOe were achieved in ($\text{Nd}_{0.95}\text{La}_{0.05}$)₁₁Fe₇₇Cr₂B₁₀. © 1998 American Institute of Physics. [S0021-8979(98)20711-0]

Because of their high remanence (B_r) and high maximum energy product [$(BH)_{\max}$], two types of nanocomposite magnets, namely, α -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$ ¹ and Fe₃B/ $\text{Nd}_2\text{Fe}_{14}\text{B}$ ^{2,3} have been widely studied for the bonded magnet application. The B_r of these nanocomposites can be strongly influenced by incorporating group II or IV elements^{4,5} and/or by the controlling of the grain size and volume fraction of α -Fe and $\text{Nd}_2\text{Fe}_{14}\text{B}$ ¹ or Fe₃B and $\text{Nd}_2\text{Fe}_{14}\text{B}$.^{2,3} Similarly, iH_c and squareness of the demagnetization curve are also strongly affected by elemental substitution and microstructure.^{4,5}

Production of precursor materials with an amorphous or nanoscaled structure and precise thermal treatment are the two key processes which determine the magnetic performance of nanocomposite materials. For α -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$ type nanocomposites, it was found that the alloy composition can ease the production of amorphous ribbons by melt spinning.⁶ Furthermore, the size and volume fraction of α -Fe and $\text{Nd}_2\text{Fe}_{14}\text{B}$ can be manipulated by thermal processing.⁷ Although $(BH)_{\max}$ values of 19–21 MGOe have been obtained on α -Fe/ $\text{Nd}_2\text{Fe}_{14}\text{B}$ -type nanocomposites,^{6,7} the corresponding iH_c obtained was normally less than 9 kOe, regardless of the method of fabrication or elemental substitution. Previously, we have shown that La and Cr substitution for Nd and Fe, respectively, in $\text{Nd}_{9.5}\text{Fe}_{81.5}\text{B}_9$ improved the iH_c of the optimized crystallized ribbons.⁸ This increase in iH_c was ascribed to the formation of Cr-rich borides in the grain boundary region which enhance the grain separations, suppress the

grain growth, and/or smooth the grain surface defects. An iH_c of 9.1 kOe and a $(BH)_{\max}$ of merely 12.5 MGOe have been obtained. It is of interest to extend this study to alloys of various boron contents to see if this trend still holds. An alloy series with compositions of (Nd,La)_{9.5}Fe_{82.5-x}Cr₂B_{6+x} ($x=0$ to 4.5) was selected for investigation.

To obtain strong exchange-coupling interaction, the volume fraction of $\text{Nd}_2\text{Fe}_{14}\text{B}$ (the hard magnetic phase) and α -Fe (the soft magnetic phase) phases must be maintained above a critical ratio.^{9–11} Although forming grain boundary phase(s) may increase the iH_c , one usually needs to balance the amount of grain boundary phase to increase iH_c with the requirement to achieve a high saturation magnetization and an effective exchange coupling. For a given boron content, varying the total rare earth content could be one of the ways to adjust the amount of $\text{Nd}_2\text{Fe}_{14}\text{B}$ and α -Fe phase to achieve this goal. For this reason, ($\text{Nd}_{0.95}\text{La}_{0.05}$)_{7.5+y}Fe_{80.5-y}Cr₂B₁₀, where $y=0, 1, 2, 3.5$ and 4, was selected for further study.

Alloy ingots with compositions ($\text{Nd}_{0.95}\text{La}_{0.05}$)_{9.5}Fe_{82.5-x}Cr₂B_{6+x} ($x=0-4.5$) and ($\text{Nd}_{0.95}\text{La}_{0.05}$)_{7.5+y}Fe_{80.5-y}Cr₂B₁₀ ($y=0-4$) were prepared by vacuum induction melting. Ingot pieces of approximately 3 grams were crushed into small pieces to accommodate the size of crucible for melt spinning. Ribbons were produced with wheel speeds (V_s) ranging from 15 to 30 m/s. X-ray powder diffraction with Cu $K\alpha$ radiation was utilized to determine the degree of crystallinity in the ribbons. Selected ribbons were thermally treated at 650–700 °C for 10 min for crystallization and to improve the permanent magnetic prop-

FIG. 1. TMA curves for crystallized $(\text{Nd}_{0.95}\text{La}_{0.05})_{9.5}\text{Fe}_{82.5-x}\text{Cr}_2\text{B}_{6+x}$ ribbons (a) $x=0$, (b) $x=3$, (c) $x=4$, (d) $x=4.2$, and (e) $x=4.5$.

erties. The magnetic phases and the corresponding Curie temperatures (T_c) were identified by a thermal gravimetric analyzer (TGA) with an externally applied magnetic field, i.e., conventionally referred to as the thermo magnetic analysis (TMA). The magnetic properties of the as-quenched ribbons and the thermally treated ribbons were measured by a vibrating sample magnetometer (VSM). Transmission electron microscopy (TEM) with energy dispersion analytical x ray (EDAX) was employed to examine the microstructure and identify the phases of the ribbons obtained.

Shown in Fig. 1 are the TMA scans of $(\text{Nd}_{0.95}\text{La}_{0.05})_{9.5}\text{Fe}_{82.5-x}\text{Cr}_2\text{B}_{6+x}$ ($x=0, 3, 4, 4.2$, and 4.5) ribbons after optimum annealing treatments. Despite the boron content being varied from 6 to 10.5 at. %, only two magnetic phases, namely, α -Fe and $\text{R}_2\text{Fe}_{14}\text{B}$, were detected. The metastable Fe_3B and $\text{R}_2\text{Fe}_{23}\text{B}_3$ phases that usually appear in the ternary boron rich Nd-Fe-B system were not detected. This suggests that La and Cr substitution may be effective in suppressing the formation of Fe_3B and $\text{R}_2\text{Fe}_{23}\text{B}_3$ phases in ribbons at least in the range of boron contents studied. Assuming that α -Fe and $\text{R}_2\text{Fe}_{14}\text{B}$ exhibit the same magnetization during TMA measurement, one may estimate the volume fractions of the α -Fe and $\text{R}_2\text{Fe}_{14}\text{B}$ phases in each ribbon by comparing the relative peak heights. In general, the volume fraction of $\text{R}_2\text{Fe}_{14}\text{B}$ in the ribbons with a higher boron content, $x=4, 4.2$, and 4.5 , is more than those with a lower boron content, $x=0$ and 3 .

Shown in Fig. 2 are the variation of B_r , iH_c , and $(BH)_{\max}$ of $(\text{Nd}_{0.95}\text{La}_{0.05})_{9.5}\text{Fe}_{82.5-x}\text{Cr}_2\text{B}_{6+x}$ ($x=0, 3, 4, 4.2$, and 4.5) ribbons after an optimum annealing treatment. At $x=0$, a B_r of 9.5 kG, a $(BH)_{\max}$ of 15.5 MGOe and an iH_c of merely 7.1 kOe were obtained. Both B_r and $(BH)_{\max}$ decrease initially with increasing boron content, then increase slightly when x was increased above 3. On the contrary, the

FIG. 2. Comparison of the magnetic properties of $(\text{Nd}_{0.95}\text{La}_{0.05})_{9.5}\text{Fe}_{82.5-x}\text{Cr}_2\text{B}_{6+x}$ ($x=0-4.5$) ribbons annealed at optimum condition.

iH_c increased initially with increasing boron content, reached a maximum of 12.6 kOe at $x=4.2$ then decreased drastically at $x=4.5$ indicating a possible phase transformation or a change of phase mixture. A B_r of 9.6 kG, an iH_c of 9.5 kOe, and a $(BH)_{\max}$ of 15.5 MGOe were obtained at $x=4.5$. This suggests that a B_r of more than 9 kG, $(BH)_{\max}$ of more than 15 MGOe, and iH_c of more than 9 kOe can simultaneously be obtained in $(\text{Nd}_{0.95}\text{La}_{0.05})_{9.5}\text{Fe}_{82.5-x}\text{Cr}_2\text{B}_{6+x}$ ribbons if x is maintained at slightly above 4. Around this boron level, the boron was surmised to react with Cr forming Cr boride(s) in the grain boundary region and freeing some Nd (and La) and Fe to form the desired $\text{R}_2\text{Fe}_{14}\text{B}$ phase. The increase of iH_c with increasing x , presumably, arises from two factors:

FIG. 3. TMA curves for crystallized $(\text{Nd}_{0.95}\text{La}_{0.05})_{7.5+y}\text{Fe}_{80.5-y}\text{Cr}_2\text{B}_{10}$ ribbons (a) $y=0$, (b) $y=1$, (c) $y=2$, (d) $y=3.5$, and (e) $y=4$.

TABLE I. Estimated volume fraction ratio of magnetic hard and soft phases ($R_2Fe_{14}B$ -type/ α -Fe ratio) of $(Nd_{0.95}La_{0.05})_{7.5+y}Fe_{80.5-y}Cr_2B_{10}$ ribbons ($y = 0$ to 4).

Composition $y =$	Peak height (arb. units)		
	Hard phase ($R_2Fe_{14}B$ type)	Soft phase (α -Fe)	$R_2Fe_{14}B/\alpha$ -Fe Ratio
0	4.498	1.260	3.57
1	2.014	0.968	2.08
2	1.387	0.701	1.98
3.5	0.945	0.736	1.28
4	0.809	0.504	1.61

the increase in the volume fraction of 2:14:1 phase^{8,12} and the increase in the amount of grain boundary phases which serves as grain separator. How to balance these two contributions is the key for successful production of nanocomposites with high iH_c and $(BH)_{max}$.

Shown in Fig. 3 are the TMA scans of $(Nd_{0.95}La_{0.05})_{7.5+y}Fe_{80.5-y}Cr_2B_{10}$ ($y = 0, 1, 2, 3.5$, and 4) ribbons after the crystallization treatment. Three magnetic phases, namely, $(Nd, La)_2(Fe, Cr)_{14}B$, $R_2Fe_{23}B_3$, and α -Fe were found in $y = 0$ and 1. However, only two magnetic phases, $(Nd, La)_2(Fe, Cr)_{14}B$ and α -Fe, were observed on $y = 2, 3.5$, and 4. The peak heights of the hard magnetic phase ($R_2Fe_{14}B$) and soft magnetic phase (α -Fe) measured by TMA scans and the estimated $R_2Fe_{14}B/\alpha$ -Fe ratio of these materials are listed in Table I. The $R_2Fe_{14}B/\alpha$ -Fe ratio decreases from 3.57 for $y = 0$ to 1.28 for $y = 3.5$ then increases again to 1.61 for $y = 4$. It is worth noting that the estimated $R_2Fe_{14}B/\alpha$ -Fe ratio only takes into account the two magnetic phases detected. Phases which were not detected by TMA scans are not included in this consideration. A detailed analytical work by TEM or microprobe is certainly needed along this aspect to confirm our hypothesis.

Shown in Table II are the comparison of B_r , iH_c , and $(BH)_{max}$ obtained for $(Nd_{0.95}La_{0.05})_{7.5+y}Fe_{80.5-y}Cr_2B_{10}$ ($y = 0, 1, 2, 3.5$, and 4) ribbons after optimum crystallization treatments. The B_r and iH_c of the ribbons with $y = 0$ and 1 are extremely low. However, these values are improved significantly when the rare earth content was increased to $y = 2$ or 3.5. A B_r of 9.5 kG, an iH_c of 13.2 kOe, and a $(BH)_{max}$ of 18.0 MGOe have been achieved on $y = 3.5$. Most importantly, an iH_c as high as 13 kOe, a B_r of more than 9.5 kG, and a $(BH)_{max}$ of 18 MGOe have been achieved. These

TABLE II. Magnetic properties of $(Nd_{0.95}La_{0.05})_{7.5+y}Fe_{80.5-y}Cr_2B_{10}$ ($y = 0 - 4$) ribbons after optimum annealing.

Composition $y =$	B_r (kG)	iH_c (kOe)	$(BH)_{max}$ (MGOe)
0	8.1	3.1	4.0
1	10.3	4.0	10.0
2	8.6	9.5	12.6
3.5	9.5	13.2	18.0
4	9.9	5.0	14.0

FIG. 4. Transmission electron micrographs of crystallized $(Nd_{0.95}La_{0.05})_{7.5+y}Fe_{80.5-y}Cr_2B_{10}$ ribbons (a) $y = 0$, (b) $y = 2$, and (c) $y = 3.5$.

high values have never been reported in either the α -Fe/ $Nd_2Fe_{14}B$ or the $Fe_3B/Nd_2Fe_{14}B$ nanocomposites.

Shown in Figs. 4(a), 4(b), and 4(c) are the TEM micrographs of ribbons with $y = 0, 2$ and 3.5 , respectively, after optimum thermal treatments. Three distinct phases, namely, $(Nd, La)_2(Fe, Cr)_{14}B$, $R_2Fe_{23}B_3$ (as the arrows indicate), and α -Fe were found in $y = 0$. Only two magnetic phases, $(Nd, La)_2(Fe, Cr)_{14}B$ and α -Fe, were detected in $y = 2$ and 3.5 . These results are consistent with TMA scans. In addition, a thin layer grain boundary phase (nonmagnetic) was found only in $y = 2$ but not in $y = 0$ and 3.5 . Moreover, the grain sizes, both the $(Nd, La)_2(Fe, Cr)_{14}B$ or the α -Fe phases, in $y = 3.5$ and 0 are finer than those in $y = 2$. The sizes of α -Fe and $(Nd, La)_2Fe_{14}B$ are estimated around 20 and 20–30 nm for $y = 3.5$ and 0, and 25 and 70–80 nm for $y = 2$, respectively. This suggests that the presence of the $R_2Fe_{23}B_3$ phase may restrict the grain growth in $(Nd_{0.95}La_{0.05})_{7.5}Fe_{80.5}Cr_2B_{10}$ and the higher La concentration in $y > 2$ may also limit the grain growth. A fine grain size is essential to induce a higher exchange coupling interaction between the 2:14:1 and α -Fe phases, resulting in a high B_r .

Anomalous high-temperature coercivities in hard nanocomposite alloys

L. H. Lewis,^{a)} J.-Y. Wang,^{b)} and D. O. Welch

Department of Applied Science, Brookhaven National Laboratory, Upton, New York 11973-5000

V. Panchanathan

Magnequench International, Inc., 6435 Scatterfield Road, Anderson, Indiana 46013

To elucidate the interphase interactions inherent to nanocomposite magnetic alloys, measurements of remanence B_r , and coercivity H_{ci} were made on a series of four meltspun, remanence-enhanced nanocomposite alloys consisting solely of various amounts of $\text{Nd}_2\text{Fe}_{14}\text{B}$ and $\alpha\text{-Fe}$. The phase constitution and microstructural scale of the alloys were characterized with synchrotron x-ray diffraction. Magnetic measurements were made using superconducting quantum interference device (SQUID) magnetometry on evacuated and encapsulated samples in the temperature range of $300\text{ K} \leq T \leq 750\text{ K}$, in order to characterize the $\alpha\text{-Fe}$ component independently of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ component. The high-temperature coercivities of the samples increase with the amount of $\alpha\text{-Fe}$ present in the samples, ranging from an average value of approximately 75 Oe for the sample with 14 wt % excess Fe to over 400 Oe at 700 K for the sample with 27 wt % excess Fe. The relatively high coercivities of the samples found at elevated temperatures imply that a tabular morphology of the $\alpha\text{-Fe}$ grains is conferring anisotropy to the phase; this conclusion is supported by transmission electron microscopy. It is concluded that while the significant coercivity of the $\alpha\text{-Fe}$ phase likely reduces the room-temperature remanence enhancement of the alloy below its theoretical ideal, the favorable interphase interface orientation promotes exchange coupling. © 1998 American Institute of Physics. [S0021-8979(98)20811-5]

I. INTRODUCTION

A detailed understanding of the nature of the interphase magnetic coupling in exchange-spring nanocomposite alloys is of paramount importance to the modeling and optimization of their performance as permanent magnets. To this end, measurements of magnetization and coercivity H_{ci} were made on a series of four meltspun nanocomposite alloys consisting solely of various amounts of $\text{Nd}_2\text{Fe}_{14}\text{B}$ and $\alpha\text{-Fe}$ using superconducting quantum interference device (SQUID) magnetometry on evacuated and encapsulated samples in the temperature range of $300\text{ K} \leq T \leq 750\text{ K}$, in order to follow the evolution of the magnetic properties as the $\text{Nd}_2\text{Fe}_{14}\text{B}$ passes from the ferromagnetic to the paramagnetic regime. The result thus obtained and expounded upon below elucidate the microstructural evolution of the alloys as increasing amounts of $\alpha\text{-Fe}$ are added to the $\text{Nd}_2\text{Fe}_{14}\text{B}$ system.

II. EXPERIMENTAL DETAILS

The alloys were made from commercial-grade materials by standard melt-quenching techniques and annealed for 4 min at 690 °C to optimize their magnetic properties. To verify the phase composition and average grain size of the alloys, synchrotron x-ray diffraction was performed on powdered samples using radiation of wavelength $0.90\text{ Å} \leq \lambda \leq 1.18\text{ Å}$, well away from the absorption edge of iron and thus preventing fluorescence. Lattice parameters were determined by a least-squares fitting program. Only two phases

were found, $\text{Nd}_2\text{Fe}_{14}\text{B}$ and $\alpha\text{-Fe}$; it is estimated that synchrotron x-ray diffraction would detect minor phases of 0.1–1.0 wt %.¹ The crystallite sizes are determined from the half-width of the Bragg peak at the half-maximum intensity position, corrected for the intrinsic broadening of the synchrotron beam, using the Scherrer formula.² The nominal compositions, lattice parameters, and the average grain size found for each constituent phase are given in Table I. The alloys are identified by their excess iron enrichment δ , defined as $\text{Nd}_2\text{Fe}_{14+\delta}\text{B}$. The specimens studied contained the following amounts of excess Fe: 1 ($\delta=0$), 14 ($\delta=4.6$), 18 ($\delta=7.2$), and 27 wt % ($\delta=9.3$). The amount of excess iron was determined from the ferromagnetic hysteretic response measured at 750 K.³ The magnetic data were obtained on packed samples evacuated to $P \approx 1 \times 10^{-6}$ Torr⁴ using a maximum applied field of 5 T in the temperature range of $300\text{ K} \leq T \leq 780\text{ K}$ with a Quantum Design SQUID magnetometer. The magnetic data were corrected for demagnetization effects, and the paramagnetic response from the 2–14-1 phase was subtracted at each measurement temperature from the corrected data to yield the saturation magnetization of the $\alpha\text{-Fe}$ phase. Room-temperature remanence ratios were calculated from corrected demagnetization extrapolated out to infinite field, Table I. Electron microscopy (TEM) was performed on the sample containing the largest amount of excess $\alpha\text{-Fe}$ ($\delta=9.3$) using a JEOL 2000 FX transmission electron microscope on dimpled and subsequently ion-milled samples.

III. RESULTS

The data in Table I indicate that the scale of the microstructure of all samples is similar, although not identical. The

TABLE I. Alloy characterization δ characterizes the iron enrichment, defined as $\text{Nd}_2\text{Fe}_{14+\delta}\text{B}$.

Stoichiometry (excess Fe wt %, δ)	Lattice parameters (\AA)	Grain sizes	Remanence (kG) at 300 K	Remanence ratios $B_r/M_s(H=\infty)$, 300 K
$\text{Nd}_{2.39}\text{Fe}_{14}\text{B}_{0.95}$ (1 wt %, $\delta=0$)	2-14-1: $a=8.804\pm0.002$ $c=12.261\pm0.005$	2-14-1: $\approx 340 \text{ \AA}$	6.3	0.53
$\text{Nd}_2\text{Fe}_{18.6}\text{B}_{2.38}$ (14 wt %, $\delta=4.6$)	2-14-1: $a=8.791\pm0.001$ $c=12.170\pm0.002$ $\alpha\text{-Fe: } a=2.86$	2-14-1: $\sim 525 \text{ \AA}$ $\alpha\text{-Fe: } \approx 175 \text{ \AA}$	8.06	0.52
$\text{Nd}_2\text{Fe}_{21.2}\text{B}_{1.65}$ (18 wt %, $\delta=7.2$)	2-14-1: $a=8.787\pm0.002$ $c=12.178\pm0.003$ $\alpha\text{-Fe: } a=2.87$	2-14-1: $\approx 340 \text{ \AA}$ $\alpha\text{-Fe: } \approx 290 \text{ \AA}$	9.21	0.56
$\text{Nd}_2\text{Fe}_{23.3}\text{B}_{1.45}$ (27 wt %, $\delta=9.3$)	2-14-1: $a=8.805\pm0.002$ $c=12.214\pm0.005$ $\alpha\text{-Fe: } a=2.88$	2-14-1: $\approx 235 \text{ \AA}$ $\alpha\text{-Fe: } \approx 180 \text{ \AA}$	10.09	0.60

grain sizes of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase are in the range of 25–50 nm, and are always larger than that of the $\alpha\text{-Fe}$ phase, which is smaller than 30 nm in all instances. There is no obvious correlation between the amount of excess iron and the precise scale of the resultant microstructure. Similarly, there is no obvious trend in the lattice parameters of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase with excess iron content, and the lattice parameter of the $\alpha\text{-Fe}$ phase agrees well with the JCPDS reference lattice parameter value for $\alpha\text{-Fe}$ of $a=2.8664 \text{ \AA}$.⁵ All samples exhibit moderate remanence enhancement and a smooth second-quadrant demagnetization curve. Figures 1 and 2 illustrate the trends of coercivity and saturation magnetization of the $\alpha\text{-Fe}$ phase, respectively, with temperature. The nominally single-phase $\text{Nd}_2\text{Fe}_{14}\text{B}$ sample exhibits a room-temperature coercivity value of 15 kOe, much higher than the coercivities of the two-phase nanocomposite samples; however, the temperature coefficient of coercivity (i.e., the slope of the coercivity versus temperature curve) is much smaller for the nanocomposite samples than it is for the single-phase sample. The inset of Fig. 1 shows an enlargement of the coercivity trend at high temperatures of the samples studied. The high-temperature coercivity measure-

ments are quite reproducible and are essentially independent of temperature. Both Fig. 1, inset, and Fig. 2 indicate that there is a direct correlation between the amount of excess $\alpha\text{-Fe}$ present in the composite and the resultant remanences and coercivities.

IV. DISCUSSION

The measured saturation magnetizations for the samples at elevated temperatures confirm that the additional Fe added to the starting composition results in the formation of increasing amounts of $\alpha\text{-Fe}$. The coercivities measured at elevated temperatures are much greater than that expected for isotropic grains of $\alpha\text{-Fe}$ with diameters under 300 \AA . If one assumes that the $\alpha\text{-Fe}$ particles are randomly oriented and reverse coherently by rotation under the influence of a demagnetizing field, the maximum coercivity expected at $T=750 \text{ K}$ is equal to $0.64 \cdot (K_1/M_s) \approx 43 \text{ Oe}$, which is approximately an order of magnitude less than the greatest coercivity measured. However, if the assumption that the particles are isotropic is relaxed, the concept of shape anisotropy may be invoked to account for the relatively large measured coercivities. The maximum coercive force that may be obtained in iron from shape anisotropy may be as high as 4300

FIG. 1. The variation of coercivity H_{c1} with temperature for the four alloys studied. Inset: Enlargement of the high-temperature portion of the graph.

FIG. 2. Saturation magnetizations at elevated temperatures of the ferromagnetic components present in the nanocomposite alloys studied.

FIG. 3. TEM micrograph of a high-Fe region of microstructure of the sample $\delta=9.3$, containing nominally 27 wt % excess iron. The arrow indicates the blocky α -Fe phase.

Oe at 750 K.⁷ The relative temperature independence of the α -Fe coercivities also supports the hypothesis that the origin of the coercivity is likely to be shape anisotropy.⁷

Electron microscopy investigations also support the conclusion that the α -Fe particles do not have the shape of randomly distributed spheres. Figure 3 is a TEM micrograph of a portion of the $\delta=9.3$ sample that shows a higher relative concentration of iron than the bulk of the sample. The blocky phase, indicated by the arrow in Fig. 3, has been identified by energy-dispersive spectroscopy to largely consist of iron and is thus identified as the α -Fe component. Although the grain size of this region is not typical of the entire sample, it does illustrate the morphology of regions with large concentrations of α -Fe. It is hypothesized that the α -Fe phase develops an increasingly tabular morphology with increasing excess Fe content in the alloys.

The data presented above have two results that are significant for the hard magnetic performance of the nanocomposites. The first result is that the coercivity of the α -Fe

component is not extremely low when both phases are in the ferromagnetic regime, as is desired for optimum exchange coupling and remanence enhancement.^{8,9} If the coercivity measured at 750 K is normalized to the maximum coercivity expected at that temperature from shape anisotropy alone, extrapolation from the high-temperature data implies that the room-temperature coercivity of the α -Fe phase in the most Fe-enriched nanocomposite ($\delta=9.3$) is around 535 Oe. This conclusion implies that the entire volume of the constituent α -Fe grains is not exchange-coupled to the 2-14-1 phase, resulting in both a lower remanence enhancement and complex internal demagnetizing fields. However, the deduced elongated shape of the α -Fe precipitates in the alloy may serve to increase the remanence enhancement by realizing maximum interphase contact.

Magnetic interactions in Fe–Ba hexaferrite nanocomposite materials

M. I. Montero, F. Cebollada, M. P. Morales, J. M. González,^{a)} and A. Hernando^{b)}

Instituto de Ciencia de Materiales de Madrid—C.S.I.C., Cantoblanco, 28049 Madrid, Spain

Results are presented on the hysteretic behavior of Fe-rich, composite Ba hexaferrite–Fe samples prepared by ball milling. The most remarkable feature of these samples was the observation of loops which were displaced in the negative sense of the field axis. Similar to this, the field evolution of the isothermal and the demagnetization remanences evidenced the achievement upon the application of 8 kOe fields of nonequivalent values of both quantities. Our results are discussed considering the different magnetic hardness of the two phases forming the sample and the occurrence of interphase (dipolar) interactions. © 1998 American Institute of Physics. [S0021-8979(98)43111-6]

I. INTRODUCTION

Short range exchange and long range dipolar interactions are crucial in determining the hysteretic properties of many real magnetic materials, for example, the achievement of extreme softness in melt spun, partly crystallized FeSiBCuNb alloys or the induction of remanence enhancement in nanocrystalline, NdFeB-based alloys. In the first case the basic softening mechanism is the average, down to a reduced effective value, of the grain magnetocrystalline anisotropy of large sets of exchange and dipolarly coupled grains.¹ The remanence enhancement, observed in hard isotropic materials, is also related to the occurrence of strong intergranular exchange which helps to keep the magnetization direction of the nanograins away from their local easy axis and close to the internal field direction.² The influence of interactions on the extrinsic properties is specially relevant in the case of composite materials where it has been predicted³ (and experimentally tested in some particular cases) that the coupling of several magnetic phases could result in extremely soft⁴ or hard properties.⁵ There are, however, two relevant obstacles to overcome in order to achieve some degree of control of the interactions and, through this, to improve the behavior of known materials for particular applications. On one hand, the absence of experimental techniques allowing one to measure interactions at a local level⁶ and on the other, the lack of a simple but realistic description of the influence of the dipolar coupling on the magnetization reversal mechanisms⁷ (dipolar interactions have a many-body nature, making them unsuitable to be analyzed in mean field terms). The aim of the present work is to contribute to the description of the phenomenology associated with the presence of interactions. For this purpose we will present data on a composite material formed by nanosized Ba hexaferrite particles and micronsized Fe ones where the interphase interactions are, exclusively, of the dipolar type.

II. PREPARATION OF SAMPLES AND EXPERIMENTAL TECHNIQUES USED

We have prepared nanocomposite samples with nominal compositions given by $\text{Fe}_x/(\text{BaFe}_{12}\text{O}_{19})_{1-x}$, where x (x

$=0.7$ and $x=0.9$) denoted a volume fraction. The samples were prepared by milling for 2 h in ball mill appropriate mixtures of Fe (45 μm average particle size) and Ba hexaferrite [30 nm average particle size, according to the measurement of the (0001) reflection half maximum width] powders. The precursor Ba hexaferrite particles were obtained by synthesis using a water-in-oil microemulsion.⁸ The phase distribution of the as-milled samples was checked through x-ray diffraction (XRD). The study of the hysteretic properties of both the precursor Ba hexaferrite and the composite samples was performed in press-powder cylinders (3 mm height \times 3 mm diameter) by using a vibrating sample magnetometer.

III. EXPERIMENTAL RESULTS

Figure 1 shows the x-ray diffractogram taken in different as-milled Fe–Ba hexaferrite composite samples. As observed in the figure the only detected reflections were those corresponding to α -Fe. (The diffractograms did not show any indication of the presence in the milled materials of phases different from the precursor ones.)

In Fig. 2 we present the room temperature demagnetization branch of the hysteresis loop measured in the starting Ba hexaferrite particles. The inset in that figure shows the field dependence of the associated differential susceptibility. The critical field of the precursor Ba hexaferrite (demagnetizing field for which a differential susceptibility maximum is mea-

FIG. 2. Demagnetization curve measured, at room temperature, in the starting Ba hexaferrite particles. Inset: field dependence of the associated differential susceptibility.

sured) was of 6225 Oe. Upon milling, the different samples exhibited, at all the considered temperatures, smooth demagnetization curves indicating the occurrence of coupling between the two present magnetic phases. In Fig. 3 we present a loop measured at room temperature and with a maximum applied field of 8 kOe in the $x=0.9$ sample. Very interestingly, the loop was measurably displaced (36 Oe) in the sense of the negative fields (see the inset in Fig. 3). The magnitude of this displacement decreased with the decrease of the Fe volume percentage. In the upper inset in Fig. 3, we present the evolution with the applied demagnetizing field of the room temperature differential susceptibility measured in the $x=0.9$ sample. The demagnetization of the softest (α -Fe) regions of the sample originated from the low field peak after which the susceptibility monotonously decreased. A comparison of the behavior observed in the precursor Ba hexaferrite particles with that measured in the composite samples showed that the field range in which the demagnetization of the hard phase proceeded was, in both cases, clearly different, whereas in the case of the precursor powders (Fig. 2) that range spanned ~ 4000 Oe around the critical field, in the case of the composite samples (Fig. 3) the demagnetization took place due to the Fe-Ba hexaferrite interactions in a much wider field region starting at fields of the order of those involved in the α -Fe reversal and spanning up to 12 kOe.

FIG. 3. Hysteresis loop measured, at room temperature, in the $x=0.9$ sample. Upper inset: field dependence of the associated differential susceptibility.

FIG. 4. Isothermal and demagnetization remanences curves measured, at room temperature, in the samples $x=0.9$ and $x=0.7$. Insets: associated δ_M plots.

Our results for the field evolution of the isothermal, M_i , and demagnetization, M_d , remanences are presented in Fig. 4. [M_i was measured by increasing (starting from the demagnetized state) the maximum applied field up to 8 kOe and M_d was obtained by first saturating the sample under a magnetizing 8 kOe field and then applying increasing demagnetizing fields down to -8 kOe.] In Fig. 4 it is observed in both samples that the 8 kOe isothermal and demagnetization remanences are different. As a consequence of this asymmetry, the delta plots (see the insets in Fig. 4 where we have represented the field evolution of the quantity $\delta_M = [M_d(H)/M_i(8 \text{ kOe})] - \{1 - 2[M_i(H)/M_i(8 \text{ kOe})]\}^9$) evidenced the occurrence of positive (magnetizing) interactions in the high field range. The magnitude of the high field δ_M value decreased with the increase of the Ba hexaferrite volume percentage.

IV. DISCUSSION

The preparation procedure and the absence (in the diffractograms taken in the Fe-rich samples) of any Ba hexaferrite reflection led us to suppose that in these samples the Ba hexaferrite particles were fully embedded in the much larger α -Fe ones. We also will assume that the only interaction between both phases was the dipolar one. This assumption was supported by the characteristics of the preparation procedure of the composite samples (which does not result in

intimate phase contact) and by the absence of any milling process-induced secondary phase. In particular we have not detected any Fe oxide which, considering the resolution of the x-ray diffraction, could be nevertheless present in small amounts. We would like to note that our Fe particles are large (they have typical dimensions of the order of tens of μm) and therefore their reversal process should not be significantly influenced by a possible exchange induced anisotropy related to the occurrence of surface oxides. Thus, we propose that the observed loop displacement and remanence asymmetry should result from the local fields, created in the soft regions of the samples by the Ba hexaferrite particles. Let us remark in this sense that the loop in Fig. 3 is not a saturation one: the maximum applied field is smaller than the field for which the demagnetization differential susceptibility of the samples goes to zero (that maximum field and those applied in the remanence measurements are, nevertheless, much larger than the field for which the α -Fe reverses its magnetization). Therefore, for the fields considered in the remanence measurements a substantial fraction of the Ba hexaferrite particles are unreversed, that is, have magnetic moments still pointing along the hemisphere centered along the direction of the initial magnetizing field. Our point is that, when both phases are close to saturation, the stray fields created by the Ba hexaferrite nanoparticles originate significant fluctuations of the local internal field inside the α -Fe particles. The magnitude of those fluctuations depends of the relative orientations of the magnetizations of the α -Fe and Ba hexaferrite particles. If we assume, for instance, that the presence of a single platelet-shaped Ba hexaferrite particle is embedded in the central region of a spherical α -Fe one with the magnetization vectors of both particles perpendicular to the bases of the platelet and pointing in the same sense (see Fig. 5), the (demagnetizing) dipolar field in the α -Fe region close to the bases of the platelet is lower than that existing in the same region if the Ba hexaferrite particle was absent. (There are also regions close to the platelet lateral surface where the local demagnetizing field is increased but, due to the platelet geometry, the volume of these regions is smaller than that corresponding to the regions where the demagnetizing field decreases.) The (predominating) decrease of the local dipolar field results in a coercivity increase (a shift in the negative field sense of the hysteresis loop). Conversely, if the magnetization of the α -Fe particle were already reversed and, as in our remanence experiments, that of the Ba hexaferrite platelet were still pointing along the original saturation direction, the dipolar field created by the hard particle reinforces that associated to the poles in the surface of the

FIG. 5. Simplified scheme of the internal field in a spherical α -Fe particle with a single platelet-shaped Ba hexaferrite particle embedded in its central region.

soft particle, resulting in an easier α -Fe reversal. In terms of energy, our simplified description of the influence of the dipolar interactions in the reversal process can be summarized by stating that when the moments of the α -Fe particle and the Ba hexaferrite platelet point parallel, the dipolar energy of the composite particle is clearly lower than that stored by if both moments point antiparallel. We also would like to propose that, since the Ba hexaferrite particles have typical dimensions corresponding to, approximately, one third of the α -Fe domain wall width, the local dipolar field fluctuations should predominantly influence the nucleation process. The nucleation field is minimized if the wall is originated around defects having transverse dimensions of the order of the 25% of the total domain wall width,¹⁰ whereas the pinning effects should predominantly be linked, for the dimensions of our Ba hexaferrite particles, to the spatial fluctuations of the particle density.

In contrast to ferromagnets, where low frequency surface excitations typically have frequencies in the 10 GHz range, surface excitations in antiferromagnets are often in the several hundred GHz to few THz range. Theoretical predictions for surface spin waves on antiferromagnets indicate that they should be highly nonreciprocal, i.e., the properties of a wave with wave vector $+k$ would be very different from those with a reversed wave vector of $-k$. Surface spin waves on antiferromagnets have recently been measured using a high resolution Fourier transform infrared spectrometer. The results show evidence of both true surface modes and surface resonances. The nonreciprocal features of the surface modes are seen in a dramatic nonreciprocal reflection. For example, the reflectivity can be 80% for one orientation, but when the incident and reflected waves are reversed the reflectivity drops to near zero. While the initial measurements were done on a bulk antiferromagnet, we also present calculations showing the results for thin films. © 1998 American Institute of Physics. [S0021-8979(98)36811-5]

The properties of antiferromagnets have recently received renewed attention for a variety of reasons. Many antiferromagnets are insulators and therefore have very different properties from the thoroughly studied ferromagnetic metals of Fe, Ni, and Co. For example, anisotropy fields in antiferromagnets are often in the 100 kG range compared to the 1 kG or less found in the transition metals. Also, antiferromagnets play an important role in the exchange biasing¹ of ferromagnetic films, a feature of current importance in magnetoresistive reading heads.² Again in contrast to ferromagnets, antiferromagnets can have long-wavelength spin excitations in the infrared (IR) frequency regime. This makes antiferromagnets of interest for signal processing in the infrared.

In this paper we report on theoretical and experimental studies of the infrared reflectivity from a bulk antiferromagnet sample of FeF₂. We concentrate in particular on the surface spin waves that propagate in this structure. In contrast to the bulk waves, the surface waves show significant nonreciprocity³ in that reversing the wave vector can significantly change the frequency of the excitation when the system is in the presence of an external magnetic field. In a reflectivity experiment this corresponds to interchanging the incident and reflected waves, and a nonreciprocal reflectivity is also observed.

We also indicate the possibility of IR studies of thin antiferromagnetic films by theoretical calculations. In very thin ferromagnetic films, it is the surface waves which will have the lowest frequencies and which are most easily measured. This is likely to be true in antiferromagnets as well,

and our initial calculations show that it should be possible to see signals from antiferromagnetic films with thicknesses in the 100–1000 Å range.

In the long-wavelength limit the reflectivity of a magnetic insulator is governed primarily by the frequency dependent permeability tensor. For the antiferromagnet, a calculation of this tensor begins with the equations of motion for the spins on the two sublattices:

$$\frac{d\mathbf{M}_1}{dt} = \gamma(\mathbf{M}_1 \times \mathbf{H}_1^{\text{eff}}), \quad (1)$$

and

$$\frac{d\mathbf{M}_2}{dt} = \gamma(\mathbf{M}_2 \times \mathbf{H}_2^{\text{eff}}). \quad (2)$$

In the above equations \mathbf{M}_1 and \mathbf{M}_2 are the magnetizations on the two sublattices, γ is the gyromagnetic ration, and \mathbf{H}^{eff} is an effective field acting either on sublattice 1 or 2.

The effective field is composed of a number of contributions. For example the effective field acting on sublattice 1 is given by

$$\mathbf{H}_1^{\text{eff}} = \mathbf{H}_1^{\text{exchange}} + \mathbf{H}_1^{\text{anisotropy}} + \mathbf{H}_0 + \mathbf{h}_{\text{dipolar}}, \quad (3)$$

with a similar expression for the effective field on sublattice 2. Here H_0 is the applied field. The exchange field is typically the largest of all the fields above with a magnitude on the order of 100–1000 kG. A key point to notice is that the exchange field acting on sublattice 1 comes primarily from the magnetization on sublattice 2, i.e.,

$$\mathbf{H}_1^{\text{exchange}} = \lambda \mathbf{M}_2, \quad (4)$$

where λ is the exchange coupling constant. Even in the long-wavelength limit, the two sublattices do not have to be par-

^{a)}Electronic mail: rcamley@brain.uccs.edu

allel and as a result the large exchange field produced by sublattice 2 influences the motion of sublattice 1 through Eq. (1).

The large exchange field is a significant difference between the ferromagnet and the antiferromagnet and explains why antiferromagnet excitations lie in the infrared while long-wavelength ferromagnetic spin wave frequencies are in the few GHz region. In the ferromagnet—in the long wavelength limit—the exchange field is simply proportional to the magnetization:

$$\mathbf{H}^{\text{exchange}} = \lambda \mathbf{M}. \quad (5)$$

As a result the contribution of the exchange field in the equations of motion is zero since $\mathbf{M} \times \lambda \mathbf{M} = 0$. So even though the exchange field is very large, it does not influence the motion of the spins. In the antiferromagnet, however, the exchange field does play a role, and the resulting frequencies are much higher.

Using the expressions for the exchange field and any external and anisotropy fields, the coupled equations of motion for the two sublattices can be solved to relate the dipolar driving fields to the fluctuating magnetization. We assume a time dependence of $\exp(-i\omega t)$ for all the dynamic fields and obtain the frequency dependent susceptibility tensor defined through the equation

$$\mathbf{M} = \chi(\omega) \mathbf{h}_{\text{dipolar}}. \quad (6)$$

The frequency dependent permeability is then found through the usual definition

$$\mu(\omega) = 1 + 4\pi\chi(\omega). \quad (7)$$

The explicit form for the permeability can be found in Ref. 4. Having found the permeability, the electromagnetic modes for the antiferromagnet may be found in the usual way.⁵ One looks for wavelike solutions which satisfy Maxwell's equations inside and outside the antiferromagnet. These solutions are then matched at the surface of the antiferromagnet and this results in the dispersion relation. The reflectivity may also be calculated similarly.⁶

We note that a number of different structures and geometries have been considered theoretically in the literature. Both easy plane and uniaxial antiferromagnets have been studied, and general geometries with arbitrary directions for the applied magnetic field and for the direction of propagation have been examined. Much of this work is summarized in the review article found in Ref. 7.

We consider a geometry where the surface of the antiferromagnet lies in the xz plane. The results take a particularly simple form for a uniaxial antiferromagnet where the easy axis and the external field are both along the surface and parallel to each other (along the z axis), and the direction of propagation is perpendicular to the external field, i.e., in the xy plane. We look for electromagnetic waves with the electric field parallel to z and the magnetic field in the xy plane (s polarized). With no external field, one may find that the permeability tensor is given by

$$\mu(\omega) = \begin{pmatrix} \mu_1 & 0 & 0 \\ 0 & \mu_1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad (8)$$

FIG. 1. Dispersion relations for bulk and surface polaritons in FeF_2 . The frequency, $\omega/2\pi c$, is given in wave numbers. The applied field is zero and so both bulk and surface modes are reciprocal, i.e., $\omega(+k_x) = \omega(-k_x)$. Propagation is perpendicular to the easy axis.

where

$$\mu_1(\omega) = 1 + \frac{8\pi H_A M}{\omega_0^2 - \omega^2}. \quad (9)$$

Here ω_0 is the resonance frequency given by

$$\omega_0 = \gamma [H_A(2H_E + H_A)]^{1/2}, \quad (10)$$

and M is the saturation magnetization of one of the sublattices. In FeF_2 the anisotropy field $H_A = 197$ kG and the exchange field $H_E = 533$ kG, and $M = 0.56$ kG. With a gyromagnetic ratio of $\gamma = 0.105$ cm^{-1}/kG this gives a resonance frequency of 52.4 cm^{-1} or about 1500 GHz.

When the applied field is zero the dispersion relations have relatively simple forms. The dispersion relation for the bulk polaritons in zero field is given by the usual relation.

$$k_x^2 + k_y^2 = \epsilon \mu_1 \omega^2 / c^2, \quad (11)$$

where k_x is the component of the wave vector parallel to the surface and k_y is the wave vector component perpendicular to the surface. The dispersion relation for surface polaritons is given by an implicit dispersion relation

$$k_x^2 = \left(\frac{\epsilon - \mu_1}{1 - \mu_1^2} \right) \mu_1 \omega^2 / c^2. \quad (12)$$

The results for the bulk and surface polaritons in FeF_2 with zero applied field are shown in Fig. 1. We see two frequency regions which represent the bulk excitations. Between the bulk bands we see a surface mode which is reciprocal, i.e., the frequency does not depend on the sign of the wave vector.

A very different dispersion curve is found when there is an external magnetic field as can be seen in Fig. 2. Now there are three bulk bands. While the bulk modes are reciprocal, the surface modes are clearly nonreciprocal. For example, one mode which exists at higher frequencies for $-k_x$ has no counterpart for $+k_x$ in the same frequency range. We note that for the geometry considered here reversing the applied field is equivalent to a reversal of the propagation direction. Thus one may determine nonreciprocal propagation and reflectivity characteristics by leaving the optical setup un-

FIG. 2. Dispersion relations for bulk and surface polaritons in FeF_2 with an applied field of 3 kG. In contrast to the $H=0$ case there are now three bulk bands and the surface modes are strongly nonreciprocal.

changed and simply reversing the applied field. This is a much simpler procedure experimentally and we use this method.

Since these excitations are in the infrared, it is natural to use infrared radiation as a probe. We note that this has been done in the past using a laser at a single frequency,^{6,8} and also with a Fourier transform infrared (FTIR) system.⁹ However, none of these experiments truly identified the surface modes. There are several reasons for this. First, the frequency gap between the bulk and the surface modes is quite small, requiring a system with high frequency resolution. Second, an ordinary reflectivity measurement is normally sensitive to bulk modes and not to surface modes.

To overcome the difficulties outlined above, we have used a specially designed FTIR system with a resolution on the order of 0.01 cm^{-1} . This requires the scanning arm of the interferometer to be about 1 m long. Additional information on the interferometer may be found in Ref. 10. In addition we use the attenuated total reflection (ATR) technique which allows the external radiation to couple to the surface modes effectively.¹¹ This technique is illustrated in Fig. 3. External light is incident on a Si prism with dielectric constant $\epsilon = 11.57$. Because of the high index of the prism, the light is totally internally reflected at the base of the prism and the reflectivity, in the absence of a sample, would be unity. However, there is an evanescent wave below the prism base which can couple to electromagnetic modes in the sample. When this occurs, the reflectivity is reduced from unity since some of the energy is transferred to the sample.

FIG. 3. ATR reflectivity geometry. Reversing the incident and reflected waves reverses the direction of k_x .

FIG. 4. Experimental and theoretical ATR reflectivity as a function of frequency for FeF_2 in zero field. The broad regions of depressed reflectivity represent losses to bulk modes. The sharp dip in reflectivity represents the loss to the surface mode. The angle of incidence in the prism is 30° and the gap between the prism and the antiferromagnet is $17 \mu\text{m}$.

To understand the ATR curves, it is helpful to plot the dispersion curve representing the incident light in the prism on top of the magnetic polariton dispersion curves. When we write the dispersion relation in terms of the component of the wave vector parallel to the surface we obtain

$$k_x = (\omega/c) \sqrt{\epsilon} \sin \theta. \quad (13)$$

This gives the straight lines shown in Figs. 1 and 2 for positive and negative k_x . Where the dispersion curve (or scan line) of the incident light crosses the bulk or surface modes of the antiferromagnet, there can be a loss of energy from the incident wave to the modes of the antiferromagnet and a corresponding reduction in reflected intensity. Thus a broad region of depressed reflectivity corresponds to the existence of bulk bands, while a sharp dip at one particular frequency corresponds to a surface mode.

In Fig. 4 we plot the ATR reflectivity for the case of zero field. The temperature here and in Fig. 5 is 1.7 K. In this plot we see two broad regions of depressed reflectivity corresponding to the two bulk bands of Fig. 1. In between there is a sharp dip in reflectivity, corresponding to the surface mode, and then an increase in reflectivity corresponding to the gap between the bulk modes. It is clear that the experimental results are in very good agreement with both the theoretical calculations for ATR reflectivity and for the dispersion relations calculated in Fig. 1.

In Fig. 5 we again plot ATR reflectivity presently for a field of $\pm 3 \text{ kG}$. From the dispersion curve in Fig. 2, we expect a total of three regions of reduced reflectivity corresponding to the three bulk bands. In addition we expect sharper dips representing the surface modes. These features are all present in Fig. 5. A key feature to note is that the surface modes appear at different frequencies depending on the sign of applied magnetic field. This clearly demonstrates the expected nonreciprocity of the surface modes. It may be possible to exploit this nonreciprocity for signal processing in the infrared. For example the ATR reflectivity near 52.5 cm^{-1} is close to zero for positive field. In contrast, the wave traveling in the reversed direction (equivalent to reversing the applied field) has a reflectivity of close to 80%. Thus this system might be used as the basis for a nonreciprocal isolator in the infrared.

FIG. 5. ATR reflectivity as a function of frequency for FeF_2 with an applied field of 3 kG. The angle of incidence in the prism is 30° and the gap between the prism and the antiferromagnet is $17 \mu\text{m}$. Note the large nonreciprocity in frequency at 52.5 cm^{-1} . The smooth curves are the theoretical results and the thinner, jagged lines are the experimental results.

By doing measurements with different angles of incidence inside the prism, one can trace out the behavior of the edges of the bulk band and the position of the surface mode. In addition one can also use ordinary reflectivity. The results^{12,13} are in excellent agreement with the theoretical calculations shown in Figs. 1 and 2. Other recent reflectivity studies on FeF_2 in a different geometry also show excellent correspondence between theory and experiment.¹⁴

The properties of thin antiferromagnetic films, or of antiferromagnetic films coupled to ferromagnets in an exchange biasing configuration may be quite different from those of bulk antiferromagnets. It is therefore of interest to see whether the infrared studies of bulk materials can be extended to thin films. In Fig. 6 we plot the ordinary infrared reflectivity (not ATR reflectivity) seen from a 1000 \AA FeF_2 film on a Si substrate. If the linewidth is on the order of 500 G, the signal is small. However, if the linewidth is only 50 G the signal is quite substantial with a change in reflectivity on the order of 15%. Linewidths in antiferromagnets can vary substantially depending on the quality of the crystal. Our bulk sample showed a linewidth on the order of 400–500 G at low temperatures. However some samples have been reported with linewidths an order of magnitude or more lower.¹⁵

The current FTIR system is sensitive to about a 1% change in reflectivity. If an antiferromagnetic film has a linewidth on the order of 50 G, this would lead to the conclusion that one should be able to observe a signal from an antiferromagnetic film with a thickness of about 100 \AA . Improvements in the signal to noise ratio might therefore easily allow much thinner films to be studied. Alternatively, one could form a superlattice where the unit cell contained, say, a 100 \AA antiferromagnetic film. Ten repeats of this structure would

FIG. 6. Ordinary reflectivity from a thin FeF_2 film on a Si substrate for different linewidths. The applied field is 1.5 kG, and the angle of incidence is 45° .

give 1000 \AA of antiferromagnet. In this case a signal should be observable even with the higher linewidths.

What could be expected from studies of thin antiferromagnetic films? We know that in ferromagnets surface anisotropy fields or interfacial exchange fields can substantially change the surface spin wave frequency.¹⁶ Measurements of this frequency can then be used to determine these surface and interface parameters. Initial calculations¹⁷ show that the spin wave modes in antiferromagnets will also be sensitive to surface and interfacial properties. Thus IR probes, either with the FTIR system or with a narrow linewidth laser of thin antiferromagnetic films may be helpful in understanding the exchange biasing effect.

The electronic structure of strained and unstrained Gd(0001) has been studied with photoemission, inverse photoemission, and spin-polarized photoemission. A shift of the occupied majority and unoccupied minority surface states has been observed as a result of the strain, consistent with the phase accumulation model. There is a strain induced shift of the minority spin surface state across the Fermi level. © 1998 American Institute of Physics. [S0021-8979(98)28611-7]

Surface states may experience a shift in binding energy due to strain.¹ For magnetic surfaces the spin dependent shift of the surface majority and minority subbands near the Fermi level can result in a variation of the spin population at different wave vectors k . This will have a substantial influence on the magnetic behavior of the surface. The subject of this article is the effect of strain on the electronic structure of the surface of gadolinium. We show consistency with the effects recently demonstrated by Neuhold and Horn¹ on the surface of Ag(111).

The surface magnetism of gadolinium has been the subject of controversy over the past years, mainly as a result of the proximity of the $5d_{z^2-r^2}$, $6s$ surface states to the Fermi level. Strain substantially alters the electronic structure of gadolinium²⁻⁴ and is expected to result in a shift of the surface state binding energies. We have been able to obtain strained films of gadolinium, with an increased lattice constant of approximately 4% by growing gadolinium on the corrugated surface of Mo(112).²⁻⁴

We investigated the occupied and unoccupied electronic structure of thin films of strained and unstrained Gd(0001). Spin-polarized photoemission experiments were carried out at the new U5UA undulator beamline of the National Synchrotron Light Source (NSLS) at the Brookhaven National Laboratory in Upton, NY. The details of the experimental setups are described elsewhere.^{5,6} Inverse photoemission spectra were acquired in a different UHV system² in the isochromatic mode ($\hbar\omega = 9.4$ eV) with a Geiger-Müller tube and an electron gun based on the Zipf design.⁷ Strained and unstrained thin films of Gd, 10–40 ML thick, were grown by slow thermal deposition on Mo(112) and W(110) substrates, respectively. The surface and bulk character of the bands has been determined from chemisorption studies and photon energy dependence, while the symmetry of the bands has been ascertained from the light polarization dependence as described in detail elsewhere.²

The influence of strain on the surface electronic structure of Gd is illustrated in Fig. 1, which compares two normal emission photoemission spectra that were taken for strained and unstrained Gd(0001). Both spectra have been acquired

with a photon energy of 33 eV for films of similar nominal thickness of approximately 15 ML. The valence band of the strained Gd(0001) films is distinct from that of the relaxed films. The binding energy of the $5d$, $6s$ strained bulk bands at 1.8 eV below E_F differs from the unstrained bulk bands observed at approximately 1.5 and 0.8 eV below E_F at the surface Brillouin zone center. More significant, the narrow surface state near the Fermi level of the unstrained Gd(0001) is shifted towards higher binding energy and appears substantially broadened.

The origin of the clearly altered valence-band states and broader density of states near the Fermi level of strained Gd is revealed by the spin resolved electronic structure, shown in Fig. 2. The unstrained Gd(0001) valence band at the Brillouin zone center ($\bar{\Gamma}$) is characterized⁸ by Stoner-like exchange split $5d$ bulk bands at binding energies of approximately 1.5 (majority) and 0.8 eV (minority) and two sets of

FIG. 1. Normal emission photoemission spectra for strained (bottom) and unstrained (top) films of Gd(0001), acquired with a photon energy of 33 eV. The inset shows a comparison of a strained (bottom) and unstrained (top) Ag(111) surface from Ref. 1.

^{a)}Electronic mail: pdowben@unlinfo.unl.edu

FIG. 2. Spin-polarized photoemission spectra for strained (bottom) and unstrained (top) Gd(0001) at normal emission and approximately 145 K. The spectra were acquired with a photon energy of 34 eV. The inset schematically plots the binding energy shifts of the surface (solid) and bulk (dashed) spin subbands as a function of increased expansive strain.

spin majority and minority subbands of the surface on either side of the Fermi level. The occupied predominantly spin-mixed majority $5d_{z^2-r^2}$, $6s$ surface state is located at approximately 0.1 eV below E_F (Fig. 2) and the unoccupied minority counterpart of the surface state at approximately 0.3 eV above the Fermi level⁹ (Fig. 3) (though this is dependent on temperature well away from T_C).¹⁰

In the strained Gd films the bulk spin majority and minority subbands are found at approximately 1.8 eV binding energy at $\bar{\Gamma}$, with negligible Stoner-like exchange splitting.³ There are three features near the Fermi level (0 to 1 eV binding energy) in the valence band of the strained Gd films. Two features, the spin majority state at 0.7 eV below E_F and the spin minority state at 0.2 eV binding energy are Stoner-

FIG. 3. The unoccupied density of states for strained (bottom) and unstrained (top) films of Gd(0001). The spectra were taken at approximately 300 K. The data for the unstrained Gd has been extracted from Ref. 9. Surface and bulk features are indicated by the surface state (SS) and bulk state (BS), respectively.

like exchange split surface bands.³ The surface character of these two states has been verified by their sensitivity to small amounts of adsorbates and their two dimensionality of state. Both surface sensitive features do not disperse with changing perpendicular momentum² and are therefore confined to the two-dimensional plane at the surface. The third feature in the valence-band region near E_F , an additional bulk band of majority character, is located in the exchange splitting gap at approximately 0.4 eV binding energy at $T/T_C < 0.7$.

The two occupied bands closest to E_F , the spin minority surface subband, and the spin majority bulk band are newly introduced into the occupied density of states as a result of the strain. Both bands are found in the unoccupied region for the unstrained Gd films as seen in Fig. 3. Expansive strain within the Gd films induces a "downward" shift of the unoccupied surface state across the Fermi level. This is consistent with the absence of the surface spin minority state (0.3 eV above E_F)⁹ in the unoccupied density of states of the strained Gd films. The spin majority bulk band at 0.4 eV binding energy of the strained Gd film is postulated to originate from the unstrained bulk band, located approximately 1.5 eV above the Fermi level,⁹ at zone center, crossing the Fermi level about halfway across the zone in unstrained Gd. This shift in binding energy at $\bar{\Gamma}$ is illustrated in the inset of Fig. 2. More detailed studies of the occupied and unoccupied density of states are, nonetheless, necessary to confirm this postulate.

From our data it is clear that the spin majority $5d_{z^2-r^2}$, $6s$ surface state is shifted from 0.2 eV binding energy for the unstrained Gd films to 0.7 eV in the strained Gd(0001). A similar downward shift of 0.5 eV is observed for the spin minority counterpart, which is unoccupied for the "relaxed" Gd(0001) and found at a binding energy of approximately 0.2 eV below E_F due to strain (Fig. 2 inset). Concomitantly, the occupied spin minority (0.8 eV below E_F) and unoccupied spin majority (≈ 1.5 eV above E_F) bulk bands of unstrained Gd experience large shifts of approximately 1.0 and 1.9 eV, respectively.

The shift to higher binding energies of the Gd surface states (majority and minority) under the influence of expansive strain is in agreement with the strain induced shifts of the surface state binding energy for Ag(111),¹ which is shown in the inset of Fig. 1. There, compressive strain results in the upward shift of the sharp Ag(111) surface state across the Fermi level, where it is cut off by the Fermi function and undetectable with photoemission. In both cases the strained induced shift of the surface state(s) can be explained by the phase accumulation model.¹¹⁻¹⁴

Surface states originate from electrons confined to the top most layer of the solid, trapped in between the bulk band gap and the surface potential. A simple one-dimensional (so-called "phase accumulation") model¹¹⁻¹⁴ can be employed to roughly describe the surface state energy. This simple model considers the surface electron in a one-dimensional quantum well, confined by the image potential on the vacuum side and the bulk band gap on the crystal side. The surface state energy is then determined by the lowest allowed quantum mechanical solution of the electron wave function. The energy of the surface state thus varies proportionally to

$1/d^2$, with d being the width of the well. In the phase accumulation formalism, d is dependent, among others, on the bulk band edges¹⁵ and the work function.^{11,13} Thus the strain induced shifts in binding energy of the surface states in gadolinium can be attributed to the altered majority and minority bulk band gaps and the reduced work function of strained Gd, approximately 2.2 eV, as compared to 3.3 eV for the relaxed Gd film.

Our results provide evidence that under expansive strain both spin components of the bulk bands are modified and results in a downward shift of the surface spin subbands. A change of the in-plane lattice constant of approximately 4% yields a surface state energy shift of 0.5 eV (Fig. 2 inset). The strain induced shifts of the bulk band edges (spin majority and spin minority) of approximately 1 to 2 eV are substantially larger than those of the surface bands. The shift of each Gd surface state (one in the spin majority band structure, the other in the spin minority band structure) is consistent with the observations and calculation for Ag(111).¹

This study shows that strain can significantly alter the spin-polarized electronic structure of a ferromagnetic system like gadolinium in much the same way as strain affects a nonmagnetic system like Ag(111). In a ferromagnetic system, we need to consider each surface state spin component in the appropriate spin-resolved band structure. It is only apparent in the spin-resolved band structure how similar the influence of strain is in both Ag(111) and Gd(0001).

Effect of surface roughness on magnetization reversal of Co films on plasma-etched Si(100) substrates

M. Li,^{a)} Y.-P. Zhao, and G.-C. Wang

Department of Physics, Applied Physics, and Astronomy, Rensselaer Polytechnic Institute, Troy, New York 12180-3590

H.-G. Min

Department of Physics, Hong-Ik University, Seoul 121-791, Korea

Co films ~ 970 Å thick were deposited, *simultaneously*, on ten plasma-etched Si(100) substrates with various etch times t . The surface morphologies and magnetic properties of the Co films were measured by atomic force microscopy (AFM) and magneto-optic Kerr effect (MOKE) technique. The analysis of the AFM images shows that as the etch time t increased from 0 to 100 min, the vertical interface width w increased from ~ 5 to ~ 1400 Å; the lateral correlation length ξ increased from ~ 300 to $\sim 10\,500$ Å. The MOKE measurements provided the in-plane azimuthal angular dependence of the hysteresis loops and the change of loop shapes with the surface roughness. It was found that the magnetization reversal process changed with the surface roughness. Magnetization rotation dominated the magnetization reversal for the smoothest films. As the films roughened, the domain-wall pinning set in, eventually dominating the magnetization reversal for the roughest films. Additionally, the magnetic uniaxial anisotropy in the Co films disappeared as the roughness parameters increased. It was also found from MOKE that the surface roughness strongly affected the coercivity. © 1998 American Institute of Physics. [S0021-8979(98)36911-X]

It is known that surface/interface roughness of magnetic thin films and of superlattices influences magnetic properties, such as magnetic anisotropy, coercivity, magnetoresistance, and magnetic domain structure.¹⁻³ Various works on the relationship between surface roughness and coercivity, of thin and ultrathin films, have been carried out.⁴⁻⁶ For examples, Mal'yutin *et al.*⁴ investigated the effect of surface roughness on the coercivity of chemically etched NiFeCo films (200–1000 Å thick) and found that the coercivity of the film increased with the increase of etch time. During the etching, the thickness of the magnetic film decreased and the surface roughness increased with etch time. Vilain *et al.*⁵ investigated the dependence of coercivity on the surface roughness for electrodeposited NiCo alloy films. For ultrathin films, Jiang *et al.*⁶ investigated the coercivity of ultrathin Co films on Cu(100) substrate versus substrate roughness. The coercivity of the 6–7 ML Co film increases from ~ 70 Oe for deposition on an atomically flat Cu substrate, to ~ 170 Oe for deposition on a Cu substrate roughened by Ar⁺ sputtering to a (vertical) interface width of ~ 1.81 atomic-step heights. This demonstrates the sensitivity of coercivity on the surface roughness.

In addition to the surface roughness, it is known that the thickness, the composition, the crystalline structure of the magnetic film, and the preparation conditions also determine the magnetic properties of the films. Therefore, to understand the interrelationship between roughness and magnetic properties, other factors influencing the magnetic properties must be controlled. In the present study, we deposited ~ 970 Å Co films simultaneously (and thus identically) on ten plasma-

etched Si(100) substrates by thermal evaporation in high vacuum and studied the effect of the surface roughness on the magnetic properties of ~ 970 Å Co films.

Ten *n*-type Si(100) substrates were etched by plasma-etching gases (CF₄ and 4% O₂) with an etch rate of 1500 Å/min to various degrees of roughness in a standard plasma-etching chamber. The etch times t were 0, 1, 5, 10, 20, 30, 40, 60, 80, and 100 min, respectively. The surface morphologies of these roughened Si(100) substrates were imaged by atomic force microscopy (AFM) with a Si₃N₄ tip. Then, these rough Si(100) substrates were arranged on a large supporting plate in another high-vacuum chamber. The Co atoms were thermally evaporated from a crucible onto these ten Si(100) substrates simultaneously. The base pressure was 5×10^{-7} Torr and the pressure increased to 5×10^{-6} Torr during deposition. A quartz crystal monitor indicated a deposition rate of ~ 0.8 Å/s and ~ 970 -Å-thick Co films formed after about 20 min deposition. The starting substrate temperature was at the ambient temperature and the substrate temperature rose during the deposition due to the filament needed to heat the Co source. The characterizations were carried out in ambient air at room temperature. The surface morphology of the Co film was imaged by AFM. The hysteresis loops were measured by the magneto-optic Kerr effect (MOKE) technique.⁷

All of the AFM images from AFM measurements showed islandlike features with a wide distribution of sizes and separations. Figure 1 shows four typical AFM images of the ~ 970 Å Co films deposited on the plasma-etched Si(100) substrates. As illustrated by the increasing scan size for successive etch time t , the average size and separation of the features increased with increasing etch time t . For etch

FIG. 1. Four grey-scale AFM images of ~ 970 -Å-thick Co films deposited on Si(100) substrates etched for times $t = 1, 15, 30$, and 60 min. Note, the scan size increases.

times longer than 20 min, the islandlike features connected to form a networklike morphology. The roughness parameters, the (vertical) interface width w , and the (lateral) correlation length ξ can be obtained by analyzing the height-height correlation function $H(r, t)$, which can be calculated from AFM images.⁸ The vertical interface width w increased from ~ 5 to ~ 1400 Å; the lateral correlation length ξ increased from ~ 300 to $\sim 10\,500$ Å. Table I lists the roughness parameters for different etch time t .

The longitudinal hysteresis loops were measured for all of the Co films using an external magnetic field amplitude $H_0 = 128$ Oe with a frequency $f = 1.4$ Hz. For a given sample, the loop was measured as a function of in-plane azimuthal angle φ from 0° to 360° . The results indicate that the easy magnetization direction of the Co films lay in the film plane for all the samples studied here. There was in-plane uniaxial magnetic anisotropy in the Co films for etch times $t < 60$ min, whereas there was no detectable in-plane magnetic anisotropy in the Co films with the etch time $t = 60$ and 100 min.

The directions of the easy axis and the hard axis in the film plane were determined from the azimuthal angle depen-

TABLE I. The surface roughness parameters (vertical interface width w and lateral correlation ξ) of Co films vs etch time t .

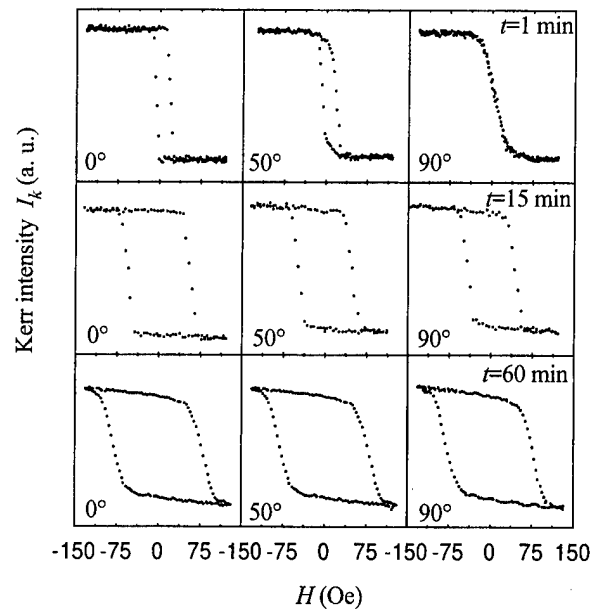

FIG. 2. MOKE hysteresis loops at three in-plane azimuthal angles (0° , 50° , and 90°) for three ~ 970 -Å-thick Co films.

dence of the loop shape. Figure 2 shows the hysteresis loops at different azimuthal angles for three typical samples with etch time $t = 1, 15$, and 60 min. For the samples with etch time $t \leq 5$ min, the shape of the loop changed from squarelike, to spindlelike, to almost a straight line as the in-plane azimuthal angle changes in the range of 0° – 90° . The loop had a squarelike shape, a high coercivity H_c and a high squareness S when the magnetic field was applied along the easy axis. When the magnetic field was applied along the hard axis direction, however, the loop was almost reversible; as a result, both S and H_c were close to zero. This suggests that the magnetization reversal process was dominated by magnetization rotation, and that the contribution to the magnetization reversal from domain wall motion was negligible for samples with $t = 0, 1$, and 5 min. The uniaxial magnetic anisotropy field can be easily obtained from the hysteresis loops.⁹

For samples with etch time $t = 10, 15, 20, 30$, and 40 min, the twofold symmetry in the coercivity versus azimuthal angle still existed, but all of the loop shapes were squarelike. The squareness lost its twofold symmetry, becoming almost constant, independent of φ . Due to the increasing surface roughness, domain-wall pinning started to contribute to the coercivity. The magnetization reversal process was associated with both the domain wall motion and magnetization rotation. To make the magnetization reversal happen in these cases, the applied field H must overcome not only the domain-wall-pinning coercivity, H_{cw} , but also the component of the magnetic anisotropy field in the applied field direction, which is $H'_a = H_a \cos \varphi$. This means that the combined magnetic field should at least equal H_{cw} . Therefore, we have the following relation:

$$H_0^2 = H^2 + H_a'^2 - 2HH'_a \cos \varphi, \quad (1)$$

where φ again is the in-plane angle between the applied

FIG. 3. The easy axis coercivity and hard axis coercivity vs etch time for ~ 970 -Å-thick Co films. The dashed curve is the fit using $H_{cw} = aw^b/\xi^c$.

field and the easy axis of magnetization, and $H'_a = (2K_u/M_s)\cos\varphi$. Letting $H_0 = H_{cw}$, and $H = H_c$, the magnetization reversal will occur, and we have

$$H_c = H'_a \cos\varphi + (H_{cw}^2 - H_a'^2 \sin^2\varphi)^{1/2}. \quad (2)$$

By using this equation, we fitted the measured angular dependence of H_c for samples with $t = 10, 15, 20, 30$, and 40 min, and obtained the magnetic anisotropy field H_a and anisotropy coefficient K_u .

For the samples with $t > 40$ min, the loop shape was squarelike, and there was no detectable in-plane magnetic anisotropy. At this point, the magnetization reversal was controlled mostly by the domain wall motion.

The results of MOKE hysteresis loop measurements suggest that the magnetization reversal process in these Co films depended strongly on the surface roughness. With the increase of the surface roughness, the magnetization reversal process changed from the magnetization rotation ($t < 10$ min) to a combination of magnetization rotation and domain-wall motion ($10 \text{ min} \leq t \leq 40 \text{ min}$), and then to domain-wall motion ($t > 40$ min).

The coercivity determined from MOKE measurements is plotted in Fig. 3 versus etch time t and for samples with $t < 60$ min, both the easy and hard axes coercivity are shown. The easy-axis coercivity H_c was, in general, a monotonically increasing function of the interface width, except for a dip around $t = 30$ min. Specifically, the H_c increased slightly between 13 and 15 Oe for $t \leq 5$ min, peaked at ~ 50 Oe for $t = 15$ min, came down to ~ 25 Oe for $t = 30$ min, then increased again to ~ 80 Oe for $t = 60$ min and ~ 70 Oe for 100 min. The hard-axis coercivity had a similar dependence on the etch time. The difference between easy axis coercivity and hard axis coercivity was due to the in-plane uniaxial anisotropy. The results indicated that H_c increased with the increase of the roughness. This is consistent with the prediction of H_c for a Bloch type of domain wall, for which H_c increases if the surface roughness increases for a given

thickness.⁹ The overall decrease of the absolute values of H_c for $t = 20$ min and $t = 30$ min samples, as compared with those of the $t = 10$ min and $t = 15$ min samples, might be due to the network formation (as in Fig. 1), which would make wall movements easier. As the etch time t increased further, the roughness increased and the H_c increased again for $t > 40$ min. We fitted the hard-axis coercivity, i.e., the domain-wall pinning coercivity by using $H_{cw} = aw^b/\xi^c$, which is shown in Fig. 3 by the dashed line.³ The roughness parameters used in the fit are the measured roughness parameters listed in Table I. The fit parameters obtained are $b = 2.40 \pm 0.05$ and $c = 1.00 \pm 0.01$. The value of fit parameter a was an order of magnitude different in two etch time ranges: $a = 0.135 \pm 0.005$ for $t < 20$ min and $a = 0.019 \pm 0.005$ for $t \geq 20$ min. This change coincides with the formation of the networklike features in the morphology after a 20 min etch. This suggests a quantitative correlation between domain-wall coercivity and surface roughness. It is expected that, as the film thickness decreases, the enhancement of the coercivity due to surface roughness would be more dramatic.

The origin of the in-plane uniaxial magnetic anisotropy is not clear yet. It might be related to the stress built up during the film deposition¹⁰ due to the different thermal expansion coefficients of the substrate and of the Co film. From MOKE measurements, the uniaxial magnetic anisotropy K_u decreased from $1.3 \times 10^3 \text{ J/m}^3$ for $t = 0$ min to 0 J/m^3 (no anisotropy) for $t = 100$ min with the increase of the etch time. A possible reason for the decrease in K_u is that, when the surface became rougher, the stress between the Co film and the Si substrate was more easily relieved. Additionally, since the dispersion of the easy axis is expected to increase with the increase of the surface roughness, the uniaxial anisotropy would average out for differently oriented crystalline grains in a polycrystalline film. It is expected that when the magnetic thin film gets thinner, the effect of the surface roughness on the magnetic properties will be more dramatic and is worth further systematic studies.

The behavior of chemical and magnetic interfaces is explored using diffuse x-ray resonant magnetic scattering (XRMS) for CoFe thin films with varying interfacial roughnesses. A comparison of the chemical versus magnetic interfaces shows distinct differences in the behavior of these two related interfaces as the chemical roughness is increased. Such changes appear to be correlated with the behavior of the magnetic hysteresis of the interface, measured by tracking the diffuse XRMS intensity as a function of applied magnetic field. © 1998 American Institute of Physics. [S0021-8979(98)17511-4]

I. INTRODUCTION

The influence of roughness on the properties of thin film magnetic structures is a question of current interest to many facets of the magnetism community. Current results have shown that direct measurements of magnetic roughness as compared to measurements of the chemical roughness indicate that these interfaces are compositionally rough, but magnetically smooth.^{1,2} Since the magnetotransport of these structures is strongly affected by interfacial scattering and in particular by magnetic disorder at the interface,³⁻⁵ chemical roughness may not be the appropriate parameter for correlation with the degradation of the magnetic properties.

The formalism for the determination of the nature of chemical interfaces and surfaces using specular and off specular (diffuse) scattering is a well established field.^{6,7} However, to probe information about a magnetic interface one needs a significant magnetic scattering signal. One way of providing this is through the resonant enhancement of the magnetic and chemical scattering when an incident circular polarized photon is tuned to an absorption edge, known as x-ray resonant magnetic scattering (XRMS).⁸⁻¹³ Utilization of a circular polarized photon, like its absorption counterpart magnetic circular dichroism (MCD),¹⁴ generates the magnetic scattering component. Recently XRMS has been applied to the study of magnetic roughness. From both specular² and diffuse¹ studies of magnetic thin film structures comes evidence of differing chemical and magnetic interfaces.

To better understand the variation of magnetic versus chemical interfaces we have undertaken a study of thin CoFe films where an increasing chemical roughness was induced through the growth process. The results clearly show that the chemical and magnetic interfaces do not behave in the same manner as the root mean square (rms) chemical roughness is increased. Also, we will demonstrate the possibility of using

variations in the magnetic diffuse intensity as a function of applied field as a probe of interfacial magnetic hysteresis.

II. EXPERIMENT

The reflectivity measurements were conducted at the NRL/NSLS Magnetic Circular Dichroism Facility located at beamline U4B of the National Synchrotron Light Source (NSLS).¹⁵ Details of the experimental apparatus and measurement conditions are described elsewhere.^{13,16} To probe interface roughness via the diffuse intensity we performed a sample rocking curve where the detector angle (2θ) was kept fixed and the sample angle (ω) was varied. In this configuration, a scan over a wave vector in the plane (q_x) is performed while keeping the component perpendicular to the film (q_z) approximately constant. To extract the magnetic information it is necessary to measure the helicity dependent scattering of the magnetic material (denoted as I^+ and I^-). So the magnetic moment of the sample was reversed at each data point to determine I^+ and I^- , which has been shown to be equivalent to alternating the photon helicity.^{17,18}

The CoFe alloys thin films were prepared by the rf sputtering facilities of Nonvolatile Electronics Inc. The samples were grown on atomically flat Si_3N_4 substrates (roughness ~ 1.5 Å rms) with the following structure: $\text{Cu}(30\text{Å})/\text{Co}_{95}\text{Fe}_5(50\text{Å})/\text{Cu}(x\text{Å})/\text{Si}_3\text{N}_4$. Due to growth dynamics the rms roughness of Cu grown on Si_3N_4 increases dramatically as the thickness of the Cu buffer layer, x , is increased. Since the Cu buffer layer thickness can be controlled accurately, the roughness of the surface on which the CoFe is deposited can be tailored. For this study we utilized a series of four films with various Cu buffer layer thicknesses ($x = 200, 400, 800, \text{ and } 1600$ Å) spanning a rms chemical roughness ranging from 2.5 to 32 Å rms as measured by a Digital Instruments Dimension 3000 atomic force microscope (AFM) in tapping mode (resolution 10–50 Å). Since the Cu cap layer is so thin, the topographical information provided by AFM should give an accurate measurement of the chemical roughness of the top CoFe/Cu interface. This will be important

FIG. 1. Sample rocking curve measured at the Co L_3 edge (778 eV) for chemical $[(I^+ + I^-)/2]$ and magnetic $(I^+ - I^-)$ contributions vs q_x . This scan was taken at a detector angle 2θ of 9° ($q_z = 0.062 \text{ \AA}^{-1}$). Notice how the half width of the magnetic diffuse (Γ_M) is smaller than that of the chemical diffuse (Γ_C), indicating a longer correlation length, ξ for the magnetic interface.

when we compare it with the diffuse scattering results because the short mean free path of the photon at the L_3 edge¹⁹ means that measurements made at grazing incidence ($\omega < 10^\circ$) for a 50 \AA CoFe film probe predominately the top CoFe/Cu interface.

III. RESULTS AND DISCUSSION

Figure 1 shows the chemical $[(I^+ + I^-)/2]$ and the magnetic $(I^+ - I^-)$ contributions from a sample rocking (diffuse) scan measured at the Co L_3 edge. The diffuse scan consists of a sharp specular peak around $q_x = 0$, with a broad underlying diffuse component. Since roughness is the mechanism that channels flux from the specular peak into the diffuse component, values for the chemical and magnetic roughness (denoted as σ_C and σ_M , respectively) can be extracted by determining the fraction of total flux that resides in the diffuse part of the spectrum. This is accomplished by comparing the integrated areas of the specular $[S_{\text{specular}}(\mathbf{q})]$ vs diffuse $[S_{\text{diffuse}}(\mathbf{q})]$ components using⁷

$$\frac{\int S_{\text{diffuse}}(\mathbf{q}) d^2 q_{\parallel}}{\int S_{\text{diffuse}}(\mathbf{q}) d^2 q_{\parallel} + \int S_{\text{specular}}(\mathbf{q}) d^2 q_{\parallel}} = 1 - e^{-(q_z \sigma)^2}, \quad (1)$$

where q_{\parallel} denotes integration over the (q_x, q_y) plane, and σ is the roughness perpendicular to the film plane. A second parameter describing the roughness in the film plane, the lateral correlation length, ξ , is determined from the half width (Γ_C and Γ_M) of the diffuse portion of the sample rocking curves using a solution of diffuse structure factor (for a roughness exponent, $h = 1$):^{6,7}

$$S_{\text{diffuse}}(\mathbf{q}) = \frac{2\pi \exp[-(q_z \sigma)^2]}{q_z^2} \times \sum_{m=1}^{\infty} \frac{(q_z \sigma)^{2m}}{m!} \left(\frac{\xi^2}{2m} \right) \exp \left[- \left(\frac{q_x \xi}{2\sqrt{m}} \right)^2 \right]. \quad (2)$$

Results of the analysis of our thickness series are shown in Fig. 2 for both chemical and magnetic data.

FIG. 2. Roughness parameters derived from the diffuse scattering data. Top panel: Chemical and magnetic rms roughness. Bottom panel: Chemical and magnetic correlation lengths.

The most important general result is the different behavior of both σ and ξ for the chemical versus magnetic interfaces. The magnetic roughness in this series of samples is $\sim 20\%$ – 30% less than the chemical roughness. The same is seen for the behavior of the chemical versus magnetic correlation length (bottom panel of Fig. 2). This indicates that the magnetic interface is typically much smoother than the chemical interface both perpendicular to and in the plane the film. There is good agreement between the σ roughness parameters extracted from the x-ray scattering and from the AFM values (the straight line of the top panel of Fig. 2). The small disagreements can be addressed through a more detailed analysis of the AFM roughness data, which is not shown here due to space limitations.

An interesting application of this technique becomes possible upon examination of the the specular versus diffuse element specific magnetic hysteresis measured by XRMS (see Fig. 3). The reflected intensity as a function of applied field can be utilized as a measure of the magnetic hysteresis since the magnetic portion of the scattering tracks with the magnetic moment of the sample. Since the field dependence specular peak intensity gives a measure of the bulk magnetic hysteresis, we can use the diffuse signal, which only comes from the interfaces, to measure the interfacial magnetic hysteresis. In Fig. 3 the clear difference in the coercive and saturation fields of spins at the interface indicates the different nature of the bulk versus interfacial magnetic environment. For the $x = 400 \text{ \AA}$ film shown in Fig. 3 the difference in coercive fields was $3.5 \pm 0.5 \text{ Oe}$. This was confirmed by measuring at not only several different points in the diffuse, but also in the specular and diffuse at different detector angles. It is worth noting that the sample indicating the large

FIG. 3. Comparison of magnetic hysteresis measured by XRMS at specular (bulk) and diffuse (interface) points for the $x=400$ Å film ($\sigma_{\text{AFM}}=10.9$ Å). Differences, such as the coercive field H_C , illustrate the different behavior of the bulk vs interfacial magnetic properties.

est difference the between specular and the diffuse coercive field is also the one exhibiting a roughening of the magnetic interface as noted by the drop in ξ_M and σ_M with respect to ξ_C and σ_C (see Fig. 2).

In conclusion, our results distinctly show that the chemical and magnetic interfaces can have a very different character. In addition, by tracking the diffuse intensity as a function of applied field we find a very different behavior of the interfacial spins, which appears to be correlated with variations of the chemical versus magnetic interface.

Soft x-ray resonant magnetic reflectivity measurements on thin films and multilayers in a *transverse* geometry using linear polarized photons are presented. Magneto-optic calculations taking into account the layer roughness allows us to reproduce all the experimental features of the angular and energy reflectivity curves as well as the asymmetry ratio in both cases. Application to $\text{Fe}_x\text{Mn}_{1-x}$ alloy films epitaxially grown on Ir(001) brings more insights on the magnetic transition occurring at $x=0.75$. © 1998 American Institute of Physics. [S0021-8979(98)49911-0]

Magnetism in artificially made materials has become an area of intense activity. The study of magnetism of ultrathin films and multilayers has revealed new properties which are different from bulk materials and have technological potential, especially in magnetic memories and magnetic based sensors. Since the devices to be implemented concern multilayered and multielement systems, it is necessary to go beyond the measurements of the macroscopic magnetic properties and to separate out the magnetic signatures of the different species within the different layers. In order to selectively probe the magnetic contributions, we develop the use of the x-ray resonant magnetic scattering (XRMS), especially in the soft x-ray range.

XRMS, which is x-ray magnetic dichroism in a scattering condition, presents the advantage of being atom and shell selective and then allows one to probe the magnetism of the different atomic levels of a specific element in a magnetic material.^{1,2} The angular dependence inherent to a scattering measurement brings furthermore the spatial selectivity. As XRMS is a two photon process, the effects related to magnetic circular dichroism (XMCD) are observable not only with circular polarized photons but also with linear polarized ones.^{3,4} Moreover, they are enhanced in diffraction conditions due to interference effects and, in that case, the magnetization dependent contribution may be of the same order of magnitude as the nonmagnetic one.⁵ This has been shown by using artificial large period structures, like Ag/Ni and Ag/NiFe multilayers, in order to diffract photons of large wavelength ($\lambda \approx 15$ Å at the Ni $L_{2,3}$ edges). These first experiments, where the energy dependence of an asymmetry ratio $R = (I^+ - I^-)/(I^+ + I^-)$ is measured, I^+ and I^- being two Bragg peak intensities collected for two opposite direc-

tions of an applied magnetic field, allowed us on one hand to demonstrate the equivalence between the XMCD and the XRMS⁶ and on the other hand to determine the amplitude of the magnetic moment of both 3d transition metals in a binary alloy.⁷ In order to study thin films, which do not give Bragg peaks at small values, we have to turn to the analysis of magnetic specular reflectivity measurements.

Following the success of XMCD measurements in the soft x-ray range, specular resonant magnetic reflectivity has been mainly measured using circular polarized incident photons in a geometry similar to the *longitudinal magneto-optic Kerr effect*.^{4,8,9} In the simulations, although general trends are well understood,⁴ some discrepancies still remain. One possible reason is related to the difficulty to take into account the roughness at the interfaces when both states of linear horizontal and vertical polarization of the photons are coupled and then to account for its effect on the change of the circular polarization rate at each interface. Therefore, we first focused on the development of the resonant magnetic reflectivity in the *transverse magneto-optic Kerr effect* geometry, using linear *p*-polarized photons. The fact that the photon beam has only one polarization state allows us to straightforwardly extend the Vidal and Vincent formalism to treat the interface roughness.¹⁰

The measurements were conducted at the *U4B* beam line at the National Synchrotron Light Source. A vacuum compatible θ - 2θ spectrometer, working in the horizontal plane, was used.¹¹ The sample was magnetized by using a Bitter electromagnet capable of delivering a field up to 1400 G perpendicular to the diffraction plane. First results were obtained from a bcc W(32 Å)/Fe(91 Å)/W(129 Å) deposited by laser ablation on a Al_2O_3 substrate. Figure 1(a) shows an angular scan where the reflected intensities and the asymmetry ratios R are collected at a selected energy in the vicinity of the L_3 Fe edge. Figure 2(a) displays an energy scan where

^{a)}Electronic mail: tonnerre@polycnrs-gre.fr

FIG. 1. Fixed energy angle scans (solid line, left side legend) and asymmetry ratio (open circles, right side legend) measured on a W/Fe/W thin film in the vicinity of Fe L_3 edge (703.2 eV): experiment (a) and calculation (b).

the angular position is kept fixed and the incident photon energy is scanned through the Fe $L_{2,3}$ edges. In this transverse geometry, the amplitude at maximum of R are typically of the order of 5% to 15% depending on both the incident angle and energy. Both scans depend on the strong resonance available at the $L_{2,3}$ edges and on the structural features of the layers: thickness and density of the layers as well as interface roughness. The energy scan is more sensitive to the spectroscopic aspect (amplitude of the magnetic moment) and the angular one to the structural aspect (arrangement of the moments).

To analyze the data, we have developed a numerical calculation based on an optical approach, where the Maxwell's equation are solved in a matrix formalism. It allows us to reproduce all the features of the experimental curve [Figs. 1(b) and 2(b)]. The main part is to calculate the dielectric tensor which only diagonal terms in a cubic dielectric and to take into account the magnetic effects through nonvanishing off-diagonal elements. Both the imaginary and real parts of the charge dielectric constant were derived from absorption data and their Kramers-Kronig transformation, respectively. Their magnetic counterparts are determined in the

same way from XMCD data obtained from thin Fe films. That amounts to consider $M_{\text{Fe}} = 2.1 \mu\text{B}$ as derived from sum rules.¹² Since it is usually accepted that XMCD is proportional to the magnetic moment, we use a multiplying factor to reduce or increase the magnetic contribution to the reflectivity in order to fit our data. More details on the calculation will be given in an upcoming article.⁷

We turn next to the discussion of an example where soft x-ray resonant magnetic reflectivity has been used to investigate the magnetic transition occurring in thin $\text{Fe}_x\text{Mn}_{1-x}$ alloy films epitaxially grown on Ir(001). While bulk alloys present a fcc structure and are antiferromagnetic (AF) over the whole range of composition, it has been shown that, in $\text{Fe}_x\text{Mn}_{1-x}/\text{Ir}$ superlattices (SL), the alloy is body-centered tetragonal (bct) and exhibit a magneto-structural transition at $x=0.75$ from a ferromagnetic state ($x>0.75$) to an antiferromagnetic one ($x<0.75$).¹³ In the present study, we focused on two superlattices $\text{Fe}_{0.9}\text{Mn}_{0.1}(27 \text{ \AA})/\text{Ir}(18 \text{ \AA})$ and $\text{Fe}_{0.7}\text{Mn}_{0.3}(27 \text{ \AA})/\text{Ir}(18 \text{ \AA})$, grown on a Ir buffer layer, whose concentrations have been chosen on each sides of the transition. In the 70% Fe sample, the alloy layer is uniformly strained all through the stacking sequence of the superlattice in a bct structure with $c/a=1.23$.¹⁴ In the 90% Fe sample, two phases have been identified.¹⁴ In the first phase, labelled SL1, the alloy and Ir layers undergo the influence of the Ir buffer layer and the alloy layer is bct with $c/a=1.16$. In the second one, SL2, both layers have relaxed the strain imposed by the buffer layer and may be considered as free layers in mutual strain. In that case, the alloy tends to the Fe bcc structure with $c/a=1.08$. The analysis of a series of reciprocal-space maps of the diffracted intensities, collected around the (111) Bragg peak of the buffer layer for different grazing incident angles, allowed us to appreciate their proportion, which corresponds to 60% and 40%, respectively, and their localization.¹⁵ These findings have been supported by the characterization of two thin alloy films of the same composition ($x=0.7$ and 0.9) with similar thicknesses ($\approx 30 \text{ \AA}$) sandwiched between Ir layers, aimed at the determination of the structural properties of the alloy layers at the beginning of the elaboration process. This is of particular interest in order to separate out the magnetic properties of SL1 and SL2.

Figure 3 shows the energy dependence of R measured at 15° on both multilayers around the Fe $L_{2,3}$ edges. The shapes of R are similar and they exhibit two resonances at the L_3 (707 eV) and L_2 edge (720 eV). Fe atoms in the Fe 90% SL give rise to a strong asymmetry ratio of about 40% while for the Fe 70% SL, R values are at most 4%. This reduction of the magnetic signal of the Fe atoms is far beyond the change one would expect from its concentration reduction. The simulation of the energy dependence of R has been carried out using the structural parameters deriving from the structural studies and by assuming that the alloy is a solid solution where the Fe atoms bear the same magnetic moment all through the layers. As in the preceding section, the magnetic moment of Fe is initially assumed to be $2.1 \mu\text{B}$. In the case of the Fe-rich SL, the calculation (solid line) fits quite well the experiment in Fig. 3(b). For the Fe 70% SL, it is required to reduce the dichroism signal by a factor 0.13 in

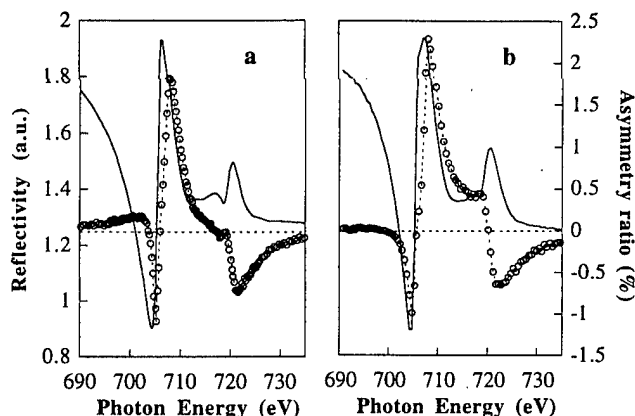

FIG. 2. Fixed angle energy scans (solid line, left side legend) and asymmetry ratio (open circles, right side legend) measured on a W/Fe/W thin film at 5° at the Fe $L_{2,3}$ edges: experiment (a) and calculation (b).

FIG. 3. Energy dependent asymmetry ratio measured at 15° at the Fe $L_{2,3}$ edges on Fe_{0.7}Mn_{0.3}/Ir (a) and Fe_{0.9}Mn_{0.1}/Ir (b): experiment (open circles) and calculation (solid line).

order to fit the data [Fig. 3(a)]. Therefore, we observe a transition for the Fe magnetic moment from 2.1 ± 0.05 to $0.27 \pm 0.05 \mu_B$. The uncertainties derive from the dispersion of the fitting parameters of reflectivity curves measured at other angular positions. It is worth recalling that the value for the Fe-rich SL is an averaged one since two phases have been evidenced in the SL. In order to separately determine the magnetic moment in the SL1 phase, we measured the energy dependence of R for the thin Fe_{0.9}Mn_{0.1} films at different angular positions. Using the same set of structural and magnetic parameters, we obtained a good agreement between experiments and calculations. Figure 4(a) shows the asymmetry ratio values obtained at 26° while the ensemble of R measurements will be published in a full article.¹⁵ Again, a fairly good agreement has been obtained with a Fe magnetic moment of $2.1 \mu_B$, leading us to conclude that the Fe atoms in SL1 and SL2 carry about the same magnetic moments. Gathering the structural and magnetic informations on the three different phases of the alloy thin films, we observe that the magnetic transition is related neither to the

FIG. 4. Energy dependent asymmetry ratio measured on Ir/Fe_{0.9}Mn_{0.1}/Ir thin film at 26° at the Fe $L_{2,3}$ edges (a) and at 20° at Mn $L_{2,3}$ edges (b): experiment (open circles) and calculation (solid line).

hypothetical fcc or bcc structure of the unstrained layer, nor to the Fe magnetic volume. It actually depends on the c/a value and the transition occurs for $c/a=1.2$ ¹⁵ which is in agreement with the theoretical prediction for a bct iron.¹⁶

Work is under progress to understand the magnetic properties of the Mn atoms. Figure 4(b) displays the weak magnetic signal measured at the $L_{2,3}$ edges of Mn in the thin Fe_{0.9}Mn_{0.1} films. It shows that Mn atoms carry a net magnetic moment. We observe the R spectrum has the same shape than that measured at the Fe L edges at the same incident angle. In order to determine the amplitude of the Mn magnetic moment as well as the coupling between Fe and Mn, we have to fit the R values. In the case of Mn, this is not so straightforward, since bulk Mn is antiferromagnetic and shows no circular dichroism. Here, the calculation is performed using the XMCD data from Mn [1 monolayer (ML)]/Fe(001),¹⁷ where the coupling is found to be ferromagnetic and the Mn magnetic moment estimated to be about $1.7 \mu_B$.¹⁸ However, to fit the R values, it has been necessary to change the sign of the XMCD data used in the calculation, which implies to consider an AF coupling of Mn moments to the Fe ones. It appears that the amplitude of the XMCD allows us to simulate the amplitude of R and, hence, we estimate the Mn magnetic moment to be about $1.7 \mu_B$.

In summary, we have shown that XRMS in *transverse mode* allows to investigate quantitatively the magnetic properties of thin films and multilayers. It turns out that it is possible to analyze small changes in the energy dependent magnetic contribution to the reflectivity. This allows us to measure weak magnetic moment (here $0.2 \mu_B$) in a thin buried layer. A refinement procedure applied simultaneously to the angular and energy scans should give more insights about the amplitude of the moments, their distribution inside the layer, and likely about the magnetic roughness at interfaces. Moreover, we show that large magnetic contributions to the reflectivity are available at large angles which should allow developments towards element specific imaging of magnetic domains. This approach could be useful for imaging the behavior of buried magnetic layers.

The authors thank Y. Souche and F. de Bergevin for fruitful discussions on magneto-optic calculations.

Dependence of anti-Stokes/Stokes intensity ratios on substrate optical properties for Brillouin light scattering from ultrathin iron films

J. F. Cochran,^{a)} M. From, and B. Heinrich

Department of Physics, Simon Fraser University, Burnaby, British Columbia V5A 1S6, Canada

Brillouin light scattering experiments have been used to investigate the intensity of 5145 Å laser light backscattered from spin waves in 20 monolayer thick Fe(001) films. The experiments have shown that the ratio of frequency upshifted light intensity to frequency downshifted light intensity depends upon the material of the substrate used to support the iron films. For a fixed magnetic field and for a fixed angle of incidence of the laser light this intensity ratio is much larger for an iron film deposited on a sulphur passivated GaAs(001) substrate than for an iron film deposited on a Ag(001) substrate. The data have been compared with a calculation that takes into account multiple scattering of the optical waves in the iron film and in a protective gold overlayer. The observations are in qualitative agreement with the theory, except for angles of incidence greater than 60°. © 1998 American Institute of Physics. [S0021-8979(98)37011-5]

The ratio of upshifted scattered light intensity (anti-Stokes line) to downshifted scattered light intensity (Stokes line) in Brillouin light scattering experiments (BLS) performed on ultrathin magnetic films depends on the optical properties of the substrate that support the film.¹ This is illustrated in Fig. 1 for BLS experiments performed on iron films 20 monolayers (ML) thick. Figure 1(a) shows scattered light intensity versus frequency shift for a 20 ML iron film grown on a Ag(001) single crystal by means of molecular beam epitaxy.² The iron film was covered by 18 ML of gold. The BLS measurements were carried out *ex situ*. A magnetic field of 1.00 kOe was applied in the plane of the film and perpendicular to the plane of incidence of the incident 5145 Å laser light. The *p*-polarized laser light was incident at 45°, and the scattered light was collected in the backscattering configuration.³ The data shown in Fig. 1(b) were collected in the backscattering configuration for *p*-polarized light^{4,5} incident at 45°, and using an applied magnetic field of 1.08 kOe. The iron film was 20 ML thick, and was grown by means of molecular beam epitaxy on a sulphur passivated GaAs(001) single crystal.⁶ The iron film was covered by 20 ML of gold and the BLS data were measured *ex situ*. It is clear from a comparison of Figs. 1(a) and 1(b) that (i) the ratio of upshifted to downshifted scattered light intensity is quite different for these two specimens; and (ii) the observed frequency shift is different for the two specimens. Both of these differences can be attributed to the effect of different substrates. The change in frequency between the two specimens can be primarily attributed to a difference in perpendicular uniaxial surface anisotropy, see Table I. The dependence of the intensity ratios on substrate material is a consequence of the dependence of the magnitude and phase of the optical electric field in the iron film on the optical properties of the substrate material. A 20 ML thick iron film is thin compared with the penetration depth of 5145 Å light in iron, consequently the optical electric field amplitudes in the iron film depend very strongly on the optical properties of the substrate.¹

Data for thin iron films grown on Ag and GaAs substrates have been compared with calculations carried out using the formalism described by Cochran and Dutcher.⁷ Relevant parameters used in the calculations are listed in Table I. The magnetic parameters listed in Table I give a good

FIG. 1. Light intensity vs frequency shift for 5145 Å light scattered from a 20 ML thick Fe(001) film; the laser light was incident on the specimen at an angle of 45°. The scattered light was collected in the backscattering configuration, and intensities were normalized to the maximum intensity of the frequency upshifted peak. (a) Ag(001)/20 ML Fe/18 ML Au with a field of 1.0 kOe applied in the film plane and directed along (100). (b) GaAs(001)/20 ML Fe/20 ML Au with a field of 1.08 kOe applied in the specimen plane and directed along (110). In both cases the magnetic field was applied perpendicular to the plane of incidence of the laser light.

TABLE I. Parameters used to calculate the frequencies and ratios of upshifted to downshifted scattered light intensities for the Ag(001)/20Fe/18Au and GaAs(001)/20Fe/20Au used for this work. The perpendicular uniaxial anisotropy energy was taken to have the form $E_u = -(K_u/d)(m_z/M_s)^2$ ergs/cc, where d is the iron film thickness and m_z is the magnetization component perpendicular to the plane of the Fe film.

Fe film:	Thickness $d = 20$ monolayers $= 28.6 \text{ \AA}$ Saturation magnetization, $4\pi M_s = 21.4 \text{ kOe}$ Exchange stiffness parameter, $A = 2.03 \times 10^{-6}$ Gilbert damping parameter, $G = 10^8 \text{ Hz}$ Optical dielectric constant, $\epsilon = (-0.40, 16.44)$ Resistivity, $\rho = 1.0 \times 10^{-5} \text{ } \Omega \text{ cm}$
(a) Ag(001)/20Fe/18Au	Cubic anisotropy parameter, $K_1 = 4.0 \times 10^5 \text{ ergs/cc}$ Uniaxial anisotropy parameter, $K_u = 1.04 \text{ ergs/cm}^2$
(b) GaAs(001)/20Fe/20Au	Effective cubic anisotropy parameter for H along (110), $K_1 = 3.7 \times 10^4 \text{ ergs/cc}$ Uniaxial anisotropy parameter, $K_u = 1.42 \text{ ergs/cm}^2$
Au film:	2.04 \AA per monolayer Optical dielectric constant, $\epsilon = (-3.75, 2.75)$ Resistivity, $\rho = 2.35 \times 10^{-6} \text{ } \Omega \text{ cm}$
Ag substrate:	Optical dielectric constant, $\epsilon = (-10.70, 0.33)$ Resistivity, $\rho = 1.59 \times 10^{-6} \text{ } \Omega \text{ cm}$
GaAs substrate:	Optical dielectric constant, $\epsilon = (17.65, 3.19)$ Resistivity, $\rho = 1 \text{ } \Omega \text{ cm}$

description of the dependence of spin-wave frequencies on applied magnetic field, see Fig. 2. The optical dielectric constants listed for 5145 Å light (2.41 eV) were obtained from Johnson and Christy (Iron,⁸ Silver⁹), Joenson *et al.*¹⁰ (gold), and Aspnes and Studna¹¹ (GaAs).

The observed upshifted to downshifted intensity ratios are plotted as a function of applied magnetic field in Fig. 3 for light incident at 45° on the specimens. The solid lines are intensity ratios calculated using the parameters listed in Table I. The data exhibit a decreasing intensity ratio with increasing magnetic field; this decrease with field is repro-

duced by the calculations. However, the calculated intensity ratios tend to be smaller than the observed ratios, especially in the case of the GaAs substrate. The calculated intensity ratios are very sensitive to the amplitudes and phases of the optical electric field components in the iron film, and these field components in turn, especially their phases, are sensitive to the film thicknesses and the dielectric parameters used to describe them.

The ratio of upshifted to downshifted light intensity has been investigated as a function of the angle of incidence of the light for fixed magnetic field. The results of angular mea-

FIG. 4. The ratio of frequency upshifted to frequency downshifted Brillouin backscattered light intensity vs the in-plane component of the spin-wave wave vector for the specimen Ag(001)/20 ML Fe(001)/18 ML Au. A magnetic field of 1.0 kOe was applied in the specimen plane along the (100) direction, and 5145 Å laser light was used for the measurements. The solid line was calculated using the parameters listed in Table I. The vertical error bars correspond to an estimated 20% uncertainty in the data.

FIG. 5. The ratio of frequency upshifted to frequency downshifted Brillouin backscattered light intensity vs the in-plane component of the spin-wave wave vector for the specimen. GaAs(001)/20 ML Fe(001)/20 ML Au. A magnetic field of 2.2 kOe was applied in the specimen plane along the (110) direction, and 5145 Å laser light was used for the measurements. (i) Calculated for a field of 1.0 kOe and (ii) calculated for a field of 2.2 kOe using the parameters listed in Table I. The vertical error bars correspond to an estimated 20% uncertainty in the data.

measurements on a specimen grown on a silver substrate are shown in Fig. 4, and results for an iron film grown on a GaAs substrate are shown in Fig. 5. The angular variation of the incident light is expressed in terms of the spin-wave wave vector component parallel with the film plane, $Q = (4\pi/\lambda)\sin\theta$, where $\lambda = 5145$ Å is the wavelength of the incident light and θ is the angle of incidence. The data exhibit an increasing intensity ratio with increasing Q , i.e., with increasing angle of incidence. The calculations, indicated by the solid lines in Figs. 4 and 5, also display an increasing intensity ratio with increasing angle of incidence. According to theory, the intensity ratio varies with angle of incidence because of an interference between the scattered light originating from the optical electric field components in the iron film that are parallel and perpendicular to the film plane. In the limit of normal incidence the optical electric field in the iron film has only a component parallel to the plane, there is no interference effect, and therefore the upshifted and downshifted intensity ratio must approach unity in the limit of $Q=0$. This expectation is borne out by the experimental observations. For reasons which we do not understand, the intensity ratio data shown in Fig. 5, and obtained using an applied field of 2.2 kOe, are in better agreement with the ratios calculated for an applied field of 1 kOe [curve (i)] than with the curve calculated using a field of 2.2 kOe [curve (ii)]. This appears to be a coincidence. However, the drop off in intensity ratio observed for Q lying between 2.0 and $2.2 \times 10^5 \text{ cm}^{-1}$ (θ between 55° and 65°), and observed for both the silver substrates and the GaAs substrates, appears to be real. It may be caused by some unknown instrumental effect. For the GaAs substrate the absolute intensity at $\theta = 65^\circ$ was also much reduced over that measured at $\theta = 55^\circ$ contrary to theoretical expectations. The origin of this rather sudden drop off in scattered light intensity is unknown: no such effect was observed for specimens grown on silver substrates. It may be associated with the observed rough iron growth obtained using a GaAs substrate.⁶ A decrease in intensity ratio at large angles of incidence runs counter to the rather sharp increase in the upshifted to down-

shifted intensity ratio for Q approximately equal to $2.25 \times 10^5 \text{ cm}^{-1}$ reported by Moosmüller, Truedson, and Patton for thin permalloy films sputtered on silicon.¹² A monotonic dependence of the intensity ratio on angle of incidence of the laser light was reported by Camley *et al.*⁵ for 100 Å thick polycrystalline iron films.

The authors would like to thank S. Watkins for the sulphur passivated GaAs substrates used in this work, and T. Monchesky for communicating to us the results of his 36 GHz microwave measurements on 20 ML Fe films grown on these GaAs substrates. We would also like to thank the Natural Sciences and Engineering Research Council of Canada for grants that supported this work.

Magnetic phase diagrams of holmium determined from magnetoresistance measurements

Jeffrey R. Gebhardt and Naushad Ali^{a)}

Department of Physics, Southern Illinois University at Carbondale, Carbondale, Illinois 62901

The magnetic phase diagrams of holmium in the magnetic field-temperature plane have been determined using electrical resistance as a function of temperature and electrical resistance as a function of applied magnetic field (magnetoresistance). Two phase diagrams were constructed corresponding to magnetic fields applied along the a and c axes. For temperatures below 80 K and an applied field along the a axis, our H - T phase diagram agrees well with that of Jensen and Mackintosh. In a temperature range of 30–100 K we observe two transitions which correspond to the boundaries of the predicted helifan phase. However, at higher temperatures there are differences with the work of Willis *et al.*, most notably in the behavior of the Néel temperature splitting. We observe a splitting of the Néel temperature above 1 T with one feature remaining nearly constant in temperature as the field is increased. For a c -axis applied field, our phase diagram is very similar to the results of Willis *et al.*, a splitting of the Néel temperature transition above 0.5 T is observed. At temperatures below 18 K and magnetic field less than 1.5 T, an anomaly associated with a devil's staircase is seen. © 1998 American Institute of Physics. [S0021-8979(98)32811-X]

The first detailed studies of the magnetic structures in holmium as a function of temperature and magnetic field, were performed by Koehler *et al.*^{1,2} using neutron diffraction. At temperatures below the Néel temperature ($T_N = 132$ K), holmium orders antiferromagnetically with a helical structure propagating along the hexagonal c axis, and with moments lying in the basal plane. Below the Curie temperature ($T_C = 18$ K), holmium restructures as a commensurate ferromagnetic cone phase. The spiral structures in the region $T_C < T < T_N$ are in general incommensurate, however, a series of commensurate magnetic phases have been found, first by Gibbs *et al.*³ using synchrotron radiation, and later by others.^{4,5} The commensurate structures in holmium are understood in terms of the spin-slip model.^{3,6} The magnetic structures in a basal plane magnetic field were studied by Koehler *et al.*² who identified intermediate phases, termed fans, between the helix and the ferromagnetic phases. Recently, a structure between the fan and helix phases, which they called a helifan, was predicted by Jensen and Mackintosh^{7,8} using mean field calculations. Some experimental evidence of this structure is given by Ohsumi *et al.*⁹ and Gebhardt *et al.*¹⁰ Bulk magnetic properties such as magnetization, Willis *et al.*¹¹ and magnetoresistance^{10,12,13} have also been used to determine magnetic phase transitions. In this article, we present the magnetic phase diagrams of holmium in the H - T plane for applied magnetic fields along the a and c axes using magnetoresistance measurements.

Two single-crystal holmium samples, each in the shape of a long bar were prepared at Ames Laboratory. The first sample has an a -axis length of 10 mm and cross-sectional

area of 0.45 mm², and the second, a c -axis length of 14.9 mm and cross-sectional area of 0.95 mm². The electrical resistance measurements were carried out using the conventional four probe method. A 30 mA longitudinal dc current was provided by a Keithley 220 constant current source, and the voltage measured using a Keithley 181 nanovoltmeter. A constant temperature and applied magnetic field was accomplished by using the temperature control and superconducting magnet of a Quantum Design SQUID magnetometer. For this study, two types of measurements were conducted: (i) the electrical resistance as a function of temperature (5–150 K) at various constant applied magnetic fields (0–5.5 T) and (ii) the electrical resistance as a function of magnetic field, defined as magnetoresistance (MR), at various constant temperatures (2–150 K).

A large number of electrical resistance (R) versus temperature (T) scans and magnetoresistance (MR) versus magnetic field (H) have been carried out for magnetic fields applied along the a and c axes of Ho. In Fig. 1(a), a representative R vs T curve is shown for a field of $H = 2$ T applied along the a axis. The transitions are indicated by arrows. The magnetic transition temperatures are determined by a step change in the R vs T curve, or as a slope change in the R vs T curve. In the inset of Fig. 1(a), the transitions are clearly seen as large spikes in the slope of R vs T curve. The anomaly at 32 K corresponds to the transition from the fan to the ferromagnetic phase. The anomalies at 80 and 86 K bracket the helifan phase predicted by Jensen and Mackintosh.⁸ These two transitions are also clearly seen in MR vs H ($H \parallel a$) curves at a constant temperature. An example is given in Fig. 1(b) for a temperature of $T = 60$ K. The transitions show as step changes in the MR vs H curve

^{a)}Corresponding author.

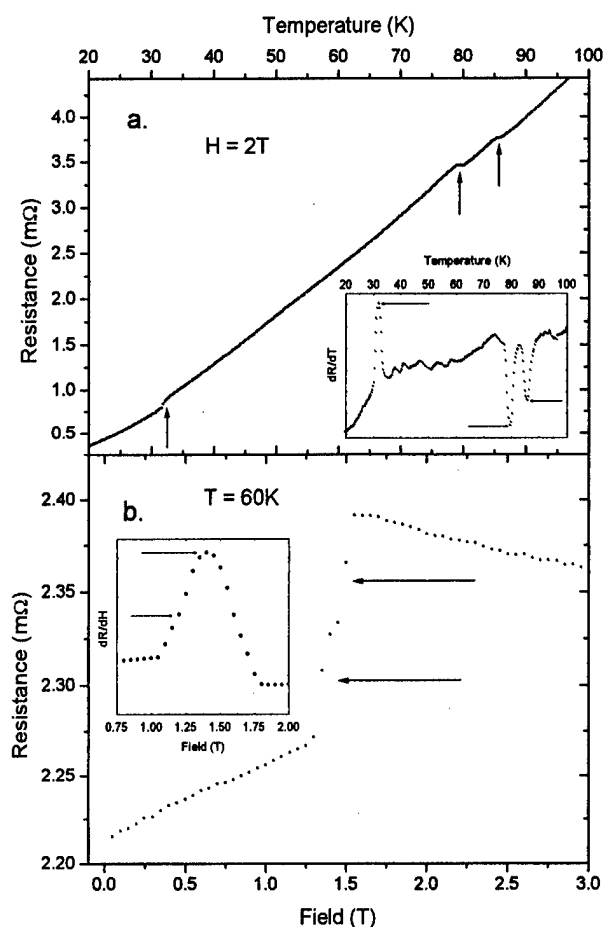

FIG. 1. (a) Resistance vs temperature for a magnetic field of $H = 2$ T applied along the a axis. The inset shows the derivative of the curve. Arrows indicate magnetic transitions. (b) Resistance vs applied field ($H \parallel a$), at a constant temperature of $T = 60$ K. The derivative is given in the inset. Arrows indicate magnetic transitions.

and are indicated by arrows. The inset of Fig. 1(b) shows the $[d(MR)/dH]$ vs H curve where the anomalies are visible in the slope change of the curve. By tabulating the transition temperatures in R vs T curves at a given magnetic field, and the transition fields in MR vs H curves at a given temperature, we are able to construct the H - T phase diagram of holmium for a magnetic field applied along the a axis of Ho.

Figure 2(a) shows a R vs T curve for a magnetic field applied along the c axis. The arrows indicate zero field anomalies at $T = 18, 20$, and 24 K. These transitions are difficult to see in the R vs T curve, but show up clearly in the slope of R vs T curve, which is shown in the inset of Fig. 2(a). The arrow marked by an asterisk refers to an anomaly which is seen in all R vs T data in applied fields from 0 T up to 5.5 T and does not vary with temperature. The anomaly is not observed in MR vs H data and does not correspond to any known magnetic phase transition in Ho. Figure 2(b) shows a MR vs H ($H \parallel c$) curve at a temperature of $T = 5$ K. Although the data is quite noisy, a large transition at $H = 1.25$ T is clearly visible in both the MR vs H , and slope of MR vs H [Fig. 2(b) inset] curves. Again, by tabulating the transition temperatures and fields, we are able to construct the H - T phase diagram of holmium for a magnetic field applied along the c axis.

The H - T phase diagram of Ho for applied field along the a axis is presented in Fig. 3. At lower temperatures, the

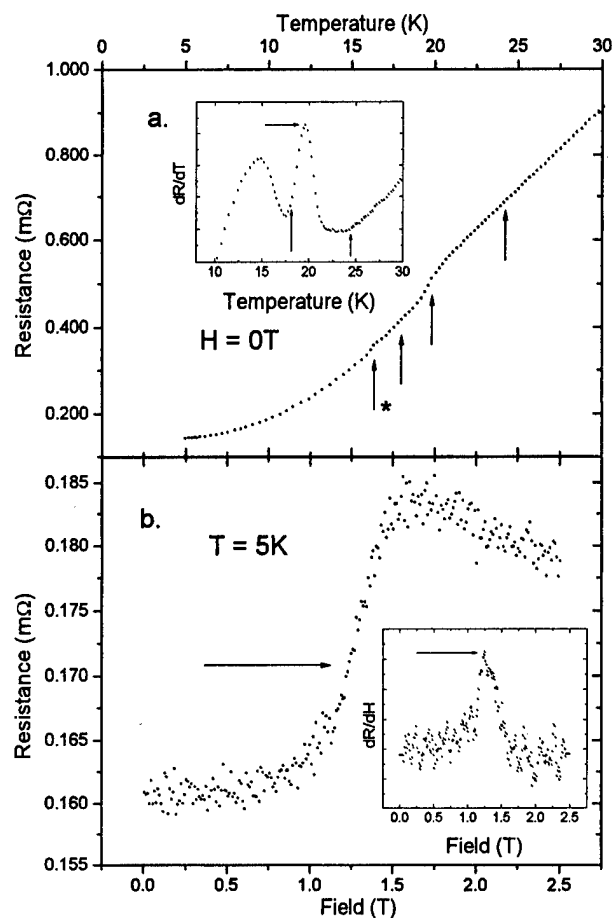

FIG. 2. (a) Resistance vs temperature measured along the c axis in zero applied magnetic field and temperatures below 30 K. The inset shows the derivative of the curve. Arrows indicate magnetic transitions. (b) Resistance vs applied field ($H \parallel c$), at a constant temperature of $T = 5$ K. The large step transition (arrow) shows as a spike in the derivative of the curve given in the inset.

phase diagram is similar to that of Willis *et al.*¹¹ determined from magnetization measurements. The inset of Fig. 3 shows our phase diagram for temperatures below 80 K and field below 2 T. This phase diagram is nearly identical to that of Jensen and Mackintosh⁸ (see Fig. 3), constructed from mean

FIG. 3. H - T phase diagram of single-crystal holmium for applied magnetic field along the a axis. Circular symbols (●) indicate data from R vs T measurements, and square symbols (■) indicate data from MR vs H measurements. Solid lines are a visual guide. The inset shows the H - T phase diagram for temperatures below 80 K.

FIG. 4. H - T phase diagram of single-crystal holmium for applied magnetic field along the c axis. The inset shows the transition associated with the devil's staircase in Ho.

field calculations and a variety of experimental data. The only exception being a transition at 42 K which merges with the lower helifan line in higher fields. The magnetic structures were labeled using the results of Jensen and Mackintosh.⁸

At higher temperatures, the phase diagram shows similarities to the phase diagram of Gebhardt *et al.*,¹⁰ also constructed from R vs T and MR vs H measurements, for applied field along the b axis of Ho. The most striking similarity is the splitting of the Néel temperature anomaly, at $T_N = 132$ K, above 1 T. This anomaly splits into two parts with one feature changing very little with temperature at higher fields, while the other shifts towards lower temperatures and merges into the lower helifan transition at about 3 T. An anomaly at 110 K shifts slightly to lower temperatures with increasing field until, above 2 T, when this shift becomes more pronounced and it merges with the lower helifan line at 2.5 T. This behavior is similar to that reported by Willis *et al.* (see Fig. 3 of Ref. 11). A transition at 98 K initially has a slight shift to higher temperatures in an increasing field, becoming more pronounced above 1 T and merging with the 110 K anomaly at 1.5 T. This result is consistent with that of Venter *et al.* (see Fig. 14 of Ref. 5), however, the pronounced shift to higher temperatures above 1 T is not evident in their phase diagram. This result also is in contradiction to the result of Willis *et al.*,¹¹ who see the 98 K anomaly shifting to lower temperatures at higher fields.

Figure 4 shows the phase diagram for a c -axis applied magnetic field. This phase diagram is very similar to the one of Willis *et al.* (see Fig. 5 of Ref. 11) determined from magnetization measurements. Zero field anomalies at $T = 18, 20, 24, 42, 98, 110$, and 131 K are observed. The anomaly at $T_C = 18$ K shifts towards lower temperatures as the field is increased, reaching 1.5 T at our lowest attained temperature of 2 K. This transition is shown in the inset of Fig. 4. The dominant wave vectors in the regions above and below the transition are labeled using the results of Venter *et al.* (see

Fig. 8 of Ref. 5), who observed a similar transition using neutron scattering. Higher field transitions for temperatures below 15 K, separating the commensurate structures of a devil's staircase, Cowley *et al.*¹⁴ could not be resolved in this study. The anomaly at 20 K has a slight shift to higher temperatures as the field is increased, until above 4 T when it splits into two parts. One part changing little with temperature, while the other shifts towards higher temperatures in an increasing field. The 24 K transition shifts towards higher temperatures until around 3 T when this shift stops and the anomaly begins a slight shift to lower temperatures as the field is increased. Anomalies at 42 and 110 K were also detected and remain unchanged in fields up to 5.5 T. An anomaly at 98 K was also observed. This anomaly splits into two parts above 2 T, with one part showing little change in temperature as the field is increased, while the other shifts towards lower temperatures. As with fields applied along the a and b axes, for a c -axis applied field, the Néel temperature anomaly at $T_N = 131$ K is seen to split into two parts. This split occurs in fields above 0.5 T which is lower than in the previous two cases. One feature does not change with an increasing field, whereas the other shifts towards lower temperatures, merging with the 110 K anomaly at 5 T.

We have constructed the H - T phase diagrams of Ho for applied magnetic fields along the a and c axes using resistance versus temperature and magnetoresistance versus magnetic field measurements. For temperatures below 80 K, our a -axis phase diagram agrees well with that of Jensen and Mackintosh.⁸ However, at higher temperatures there are discrepancies with that of Willis *et al.*¹¹ Our c -axis phase diagram agrees well with the phase diagram of Willis *et al.*¹¹

This study shows that even complicated magnetic phase diagrams can be established by simple magnetoresistance measurements. Such studies could be very useful for the location of temperature and field ranges for magnetic structure studies by neutron and or x-ray synchrotron scattering.

Magnetostatic critical point phenomena of ErGa garnet

Toshiro Tanaka^{a)} and Kazuo Miyatani

Department of Materials Science and Engineering, Ehime University, Bunkyocho 3, Matsuyama, 790-8577 Japan

The magnetostatic critical point phenomena of an ErGa garnet, $\text{Er}_3(\text{Fe}_{0.8}\text{Ga}_{0.2})_5\text{O}_{12}$, single crystal sphere were investigated by a computer controlled vibrating sample magnetometer. Subtracting the induced large spin paramagnetic moment of Er^{3+} from the measured values, allowed the Fe-sublattice magnetization $M_{\text{sub}}(H, T)$ to be extracted. M_{sub} data were used to analyze the critical phenomena by eliminating the low field data to avoid the effect of the magnetic inhomogeneity. The spontaneous magnetization and the zero-field susceptibility were obtained from the Arrot plot. The critical temperature and critical indices were obtained to be $T_c = 463.64$ K, $\beta = 0.48 \pm 0.03$, $\gamma = 1.1 \pm 0.1$, and $\delta = 3.1 \pm 0.1$. These results agree well with the predicted values from the molecular field theory. The plot of the critical equation of states $\psi(H, M)$ showed the same function as that found for Fe. Thus, $M_{\text{sub}}(H, T)$ was shown to satisfy the second-order phase transition based on the molecular field theory. © 1998 American Institute of Physics. [S0021-8979(98)23011-8]

I. INTRODUCTION

One of the present authors (K.M.) investigated the magnetostatic critical point phenomena of a yttrium-iron-garnet (YIG) single crystal¹ using the directly measured critical temperature T_c and the spontaneous magnetization $M_0(T)$. In YIG, Y^{3+} is a nonmagnetic ion and the magnetization is given by the ferrimagnetically coupled Fe^{3+} sublattice moments. The magnetostatic critical point phenomena were revealed to be close to those of the Heisenberg ferromagnet CdCr_2Se_4 ² and the metal ferromagnets Ni and Fe which we reported recently.³

The magnetization of the ErIG was explained by the ferrimagnetically coupled Fe^{3+} sublattice moments, and Er^{3+} sublattice moment weakly coupled with them.⁴ In this work, we substituted ErIG with Ga. The substituted nonmagnetic Ga^{3+} diluted the Fe^{3+} sublattice magnetization and the magnetic coupling was lowered. Then, the Er^{3+} moment should become not negligible compared to the Fe^{3+} sublattice moment. It is thus interesting to investigate the magnetostatic critical point phenomena with three sublattice moments.

II. SAMPLE AND EXPERIMENTAL PROCEDURE

A single crystal ErGa garnet, $\text{Er}_3(\text{Fe}_{1-x}\text{Ga}_x)_5\text{O}_{12}$, sphere sample (od = 3.326 ± 0.01 mm) with a polished surface was obtained from a single crystal ingot prepared by a floating zone melting method using an IR imaging furnace at the RCA Laboratories. The sphere sample was annealed at 1273 K for 10 h in air prior to the measurement. The Ga concentration x was estimated to be $x = 0.2$ from the lattice constant, the saturation magnetization at 0 K, and the density measurements.

The magnetization along an easy direction was measured using a computer controlled vibrating sample magnetometer. The temperature of the sample was measured by the cali-

brated PlatinelTM thermocouple directly contacted with its surface. The experimental procedure basically followed our recent work.³

III. RESULTS AND DISCUSSION

The temperature dependence of the magnetization measured at 8 kOe is shown in the inset of Fig. 1. The Curie temperature was about $T_c = 460$ K which was 100 K lower than the reported value of ErIG.⁴ The substituted Ga has thus lowered the average super exchange interaction between Fe^{3+} sublattices. The constant field magnetization was measured in detail from $H_a = 0$ Oe to 8 kOe at the temperatures between 440 and 520 K as shown in Fig. 1. The kink point which corresponds to the spontaneous magnetization was rounded on the curves contrary to the case of YIG¹ and the

FIG. 1. The temperature dependence of the constant field magnetization near critical temperature. The inset shows the temperature dependence of magnetization measured at 8 kOe from 20 to 500 K.

FIG. 2. Arrot plot for the measured magnetization M .FIG. 3. Arrot plot for the Fe-sublattice magnetization M_{sub} .

magnetic transition was broadened. These facts suggest that this single crystal involves a magnetic inhomogeneity which may be caused by the local strain or imperfections associated with the substitution of Fe with Ga and that the low field data are significantly affected by this inhomogeneity.

The Arrot plot, M^2 vs H_{eff}/M , for the measured data M is shown in Fig. 2. H_{eff} was given by $H_{\text{eff}} = H_a - 4\pi nM$ and n was obtained to be 0.3333 from the magnetization measurement. As is seen in the plot, M^2 is not proportional to H_{eff}/M even in high H_{eff} . This shows that the Landau theory for the second-order phase transition does not apply to the present system anymore. To understand the result, we assume that a large paramagnetic magnetization term of the Er^{3+} spin $\chi_{\text{Er}}H_{\text{eff}}$ is involved in M . This term is commonly known to exist in rare-earth iron-garnet (RIG), and should not contribute to the phase transition at T_c . The experimental data M is expressed by

$$M = M_{\text{Fe}} + M_{\text{Er}}(\text{Fe}) + \chi_{\text{Er}}H_{\text{eff}}, \quad (1)$$

where M_{Fe} is the Fe^{3+} sublattice magnetization and $M_{\text{Er}}(\text{Fe})$ is the Er^{3+} sublattice magnetization induced by M_{Fe} .

The susceptibility of Er^{3+} spin paramagnetism $\chi_{\text{Er}} = C_{\text{Er}}/(T - \theta_p)$ was estimated from the paramagnetic susceptibility χ measured at $T > T_c$. χ is given by

$$\chi = C/(T - \theta_p) = (C_{\text{Fe}} + C_{\text{Er}})/(T - \theta_p). \quad (2)$$

C_{Er} was estimated by the ratio of the total Er^{3+} and Fe^{3+} spin magnetic moment in a formula unit. The θ_p was obtained to be -10 K which was close to results of early work.⁴ Now, we can separate the Fe-sublattice magnetization M_{sub}

$$M_{\text{sub}} = M_{\text{Fe}} + M_{\text{Er}}(\text{Fe}) \quad (3)$$

by subtracting $\chi_{\text{Er}}H_{\text{eff}}$ from the experimental data M .

The Arrot plot of M_{sub} was replotted in Fig. 3 for the high field data, $H \geq 1$ kOe, eliminating the low field data. M_{sub}^2 is then found to be proportional to $H_{\text{eff}}/M_{\text{sub}}$. The spontaneous magnetization M_0 and the zero-field inverse

susceptibility χ_0^{-1} were obtained by extrapolation to the M_{sub}^2 axis and the $H_{\text{eff}}/M_{\text{sub}}$ axis, respectively. In Fig. 4, the temperature dependence of M_0 and χ_0^{-1} is shown with $M_{\text{sub}}(T)$.

The critical temperature was assumed to be 463.64 K from the T^* vs T plot⁵ where $T^* \equiv \chi_0^{-1}(T)/(\partial\chi_0^{-1}(T)/\partial T)$. The critical indices β and γ , defined as $M_0(T) = \epsilon^\beta$ and $\chi_0^{-1} = \epsilon^\gamma$ for $\epsilon = |T - T_c|/T_c$, were obtained to be 0.48 ± 0.03 and 1.1 ± 0.1 , respectively. The critical index δ defined as $M_0(H_{\text{eff}}, T_c) = H_{\text{eff}}^{1/\delta}$ was also determined to be 3.1

FIG. 4. Temperature dependence of the spontaneous magnetization and zero-field susceptibility. The dotted lines indicate the constant field M_{sub} at 1 Oe–8 kOe.

TABLE I. Critical indices and critical temperature.

	β	γ	δ	T_c (K)	Ref
ErGa garnet	0.48 ± 0.03	1.1 ± 0.1	3.1 ± 0.1	463.46	...
YIG	0.380 ± 0.005	1.312 ± 0.008	4.42 ± 0.05	551.35	^a

± 0.1 . The critical indices and the Curie temperature were listed in Table I with those for YIG, and the theoretically predicted values.⁶ The present values do not agree with those for YIG, but are close to those predicted by the molecular field theory.

The Fe-sublattice magnetization at $H_a = 2, 4$, and 8 kOe were plotted in the form of $H_{\text{eff}}/(M(T)\epsilon^\gamma)$ vs $M(T)/\epsilon^\beta$ to check the validity of the critical equation of state $\psi(M, H)$ in Fig. 5. M_{sub} below and above T_c fell on the two separate curves, respectively. This suggests that M_{sub} obeys a second-order phase transition, and $\psi(M, H)$ shows the same function as that for Fe.³

In work on YIG,¹ CdCr_2Se_4 ,² Ni ,^{1,3} and Fe ,³ M_0 and χ_0^{-1} were determined directly from the extremely low field magnetization measurements. This allowed us to investigate the magnetostatic critical point phenomena without approximation. In contrast to this, in the present work, we eliminated the low field data from M to avoid the influence of magnetic inhomogeneity which was enhanced in low fields. The magnetostatic critical point phenomena can be explained approximately by a molecular field theory. Present results show that the magnetization data at the critical region once the low field data was excluded satisfies a molecular field theory.

FIG. 5. $H_{\text{eff}}/M\epsilon^\gamma$ vs M/ϵ^β plot of M_{sub} for using $T_c = 463.64$ K in the temperature range from 463.14 to 479.14 K.

A Monte Carlo investigation of the eight-state Potts model on the two-dimensional (2D) quasiperiodic octagonal tiling with free boundary conditions is performed in order to determine the nature of a temperature-driven transition. It is shown that numerical data suffer from drastic free boundary effects that strongly disturb the probability distributions of the internal energy and, consequently, the scaling behavior of the specific heat. An alternative way consisting in analysing the core of the tilings is applied to pass over free boundary effects. This analysis combined with the Lee-Kosterlitz method allows one to evidence that the system undergoes a first-order transition as in 2D periodic lattices. The first-order type of scaling is observed for the maximum in the susceptibility of the core of the tilings but not for the maximum in the specific heat. © 1998 American Institute of Physics. [S0021-8979(98)23111-2]

I. INTRODUCTION

Recently, it has been shown by theoretical arguments that bond randomness will induce a second-order phase transition in a system that would undergo a symmetry-breaking first-order phase transition.^{1,2} Since these arguments have been derived from an actual renormalization-group calculation¹ and from a rigorous proof of the vanishing of the latent heat,² Chen *et al.*³ have investigated the ability of extensive Monte Carlo (MC) simulations to evidence such a prediction. They have considered the two-dimensional (2D) eight-state Potts model⁴ which undergoes a first-order transition when it is pure. Applying finite-size scaling techniques, they concluded that, under bond randomness, the phase transition changes from first to second order with 2D Ising exponents. These new results have motivated us to study the eight-state Potts model on 2D quasiperiodic tilings⁵ which are less ordered than periodic lattices although they exhibit long range translational order. We have considered an octagonal tiling (Fig. 1) because all octagonal tilings are locally isomorphic,⁶ that is, they exhibit identical phase transitions.

II. BACKGROUND AND NUMERICAL SIMULATIONS

The Hamiltonian of the q -state Potts model is given by⁴

$$H = -\frac{q}{q-1} J \sum_{\langle i,j \rangle} \delta_{S_i S_j} \quad (J > 0),$$

where the spins S_i , which are located at the vertices of the octagonal tiling, take on the values $1, \dots, q$ and δ is the Kronecker delta function (in this study, $q=8$).

The procedure is the importance-sampling MC method based on the standard single spin-flip Metropolis algorithm⁷ combined with the single histogram technique.^{8,9} Our simulations were carried out on finite octagonal tilings of N_{tot} vertices with free boundary conditions. In order to investigate the free boundary effects, two kinds of systems (N vertices) have been considered: systems which are the whole tilings ($N=N_{\text{tot}}=329, 689, 1433, 2481, \text{ and } 5497$), and systems which are the core of the tilings ($N \approx 0.13 \times N_{\text{tot}}=89, 329, \text{ and } 705$). This core is made up of the vertices which are located in a circle centered on the center of the tiling. Between 5×10^5 or 10^6 Monte Carlo steps (MCS)/spin for

FIG. 1. The octagonal tiling and the six local environments.

^{a)}Electronic mail: Denis.Ledue@univ-rouen.fr

$N_{\text{tot}}=329$ and 5×10^6 MCS/spin for $N_{\text{tot}}=5497$ were performed (the first 2×10^4 MCS/spin were discarded for equilibration).

The nature of a phase transition can be, in principle, determined by looking at the size dependence of some thermodynamic quantities in the vicinity of the transition temperature T_c .¹⁰⁻¹² For example, the scaling forms³ for the specific heat and the susceptibility¹² in 2D systems are, at a first-order transition:

$$C_{\text{max}}(L) \sim L^2 A(tL^2), \quad \chi_{\text{max}}(L) \sim L^2 B(tL^2)$$

and, at a second-order transition:

$$C_{\text{max}}(L) \sim L^{\alpha/\nu} C^0(tL^{1/\nu}), \quad \chi_{\text{max}}(L) \sim L^{\gamma/\nu} \chi^0(tL^{1/\nu}),$$

where $L = \sqrt{N}$ is the linear dimension of the system, α , γ , and ν are three infinite system critical exponents and $t = |T - T_c|/T_c$. However, a pseudodivergent correlation length in weak first-order transition can be responsible for a second-order type of scaling of thermodynamic quantities.¹³ A more powerful method of detecting first-order transitions by numerical simulations on finite systems is the Lee-Kosterlitz method¹⁴ which suggests to look at the size dependence of the free energy, $F_L(E) = -\ln[P_L(E)]$, where $P_L(E)$ is the probability distribution of the internal energy. For a first-order transition, the free energy for large systems at $T_c(L)$ (the location of the maximum in the specific heat) exhibits a maximum $F_L(E_2)$ between two wells of equal depth $F_L(E_1) = F_L(E_3)$. If the free energy barrier, $\Delta F_L = F_L(E_2) - F_L(E_1)$, grows with increasing system size, the transition will be first order in the thermodynamic limit, while the transition will be second order if the barrier decreases with increasing size. In MC simulations using histogram techniques, the free energy barrier can be estimated by the reweighted probability distribution at $T_c(L)$:

$$\Delta F_L = \ln[P_L(E_1)/P_L(E_2)].$$

It has been demonstrated that this method can identify unambiguously weak first-order transitions even when $L \ll \xi$ (ξ is the correlation length), at least for systems with periodic boundary conditions.¹⁴

III. RESULTS AND DISCUSSION

In order to investigate the nature of the phase transition, we plotted the size dependence of the maximum in the specific heat and the susceptibility on a log-log scale (Figs. 2 and 3). Four different linear fits were performed using system sizes $N_{\text{min}} \leq N \leq 5497$ with respectively $N_{\text{min}}=329, 689, 1433$, and 2481 . We were not able to conclude about the nature of the phase transition since the slope increases with N_{min} ($1.30 \pm 0.08, 1.40 \pm 0.09, 1.52 \pm 0.12, 1.61 \pm 0.21$ for C_{max} and $1.76 \pm 0.08, 1.8 \pm 0.1, 1.88 \pm 0.15, 1.93 \pm 0.23$ for χ_{max}) showing a nonanalytic behaviour for the two thermodynamic quantities. Then, one should keep in mind that, for a first-order transition, the L^2 behaviour can be observed only if L is larger than ξ . For example, the asymptotic regime of the 2D pure ten-state Potts model¹³ which is characterized by a small correlation length (≈ 6 lattice spacings) is reached by $L=12$. For the pure 2D eight-state Potts model, the cor-

FIG. 2. Log-log plot of the size dependence of C_{max} (the dashed line corresponds to a linear fit; where not shown, the estimated error bars are smaller than the symbols).

relation length is about 15 lattice spacings [$\xi(q=8) \approx 2.5 \times \xi(q=10)$].¹⁵ So, if we assume that the correlation length is roughly the same in the octagonal tiling as in the square lattice, we should observe the L^2 behavior since $L_{\text{max}} \approx 74$ in this study ($N_{\text{max}}=5497$). On the other hand, let us remind that the asymptotic regime of the 2D random-bond eight-state Potts model is reached approximately by $L=28$.³ So, the asymptotic regime should be observed too if our system undergoes a second-order transition. In order to get more information, we plotted the probability distributions of the internal energy at $T_c(L)$ that can be very useful to determine the nature of a transition (even if $L \ll \xi$).¹⁴ Unfortunately, they do not allow to conclude either. Indeed, for $N \leq 1433$, they look like single-Gaussian distributions which should suggest a second-order transition but they clearly exhibit a

FIG. 3. Log-log plot of the size dependence of χ_{max} (the dashed line corresponds to a linear fit).

FIG. 4. Probability distributions of the internal energy for $N=N_{\text{tot}}=689$ at $kT/J=0.8550$ (single-Gaussian distribution) and for $N=705$ and $N_{\text{tot}}=5497$ at $kT/J=0.8730$ (double-Gaussian distribution).

shoulder for $N=2481$ and 5497 . These unusual shapes for the probability distributions suggest that our numerical data are strongly disturbed by free boundary effects.

To clarify the question about free boundary effects, MC data from the simulations with $N \approx 0.13 \times N_{\text{tot}}$ are presented below (analysis of the core of the tiling). For a given N , C_{max} , and χ_{max} , increase with N_{tot} (Figs. 2 and 3) indicating that the internal energy and the order parameter fluctuations in the vicinity of the transition are more important as the free boundary effects lower. This can be seen on the probability distributions of the internal energy which evidence that low energy states corresponding to the ordered phases are occupied for the systems with $N \ll N_{\text{tot}}$ but are missing if $N = N_{\text{tot}}$ (Fig. 4). Moreover, the probability distributions look like double-Gaussian distributions. The estimated free energy barrier increases with size N [$\Delta F(N=89)=0.08 \pm 0.03$, $\Delta F(N=329)=0.19 \pm 0.05$, and $\Delta F(N=705)=0.38 \pm 0.05$] indicating that the phase transition is first order as in 2D periodic lattices. Note that the slope of the linear fit of the size dependence of C_{max} and χ_{max} are, respectively, 1.37 ± 0.03 and 2.02 ± 0.02 (Figs. 2 and 3). So, the size dependence for χ_{max} is consistent with a first-order transition whereas the one for C_{max} is difficult to explain.

In order to estimate the infinite tiling transition temperature,^{12,13} we investigated the dependence of the location of χ_{max} vs L^{-2} for the three simulations with $N \approx 0.13 \times N_{\text{tot}}$. Two linear fits, using either the three data points or discarding the point $N=89$, provided, respectively, kT_c/J

$=0.8745 \pm 0.0015$ and 0.8757 ± 0.0006 which are in good agreement. Note that these two estimates are also consistent with those obtained from the size dependence of the location of C_{max} , that is, $kT_c/J=0.875 \pm 0.001$ and 0.8760 ± 0.0007 . So, the transition temperature of the eight-state Potts model on the octagonal tiling (mean coordinence $\langle z \rangle = 4$) is slightly higher than on the square lattice ($kT_c/J=0.8513$).⁴ This higher tendency to ferromagnetic ordering in quasiperiodic tilings has already been observed in previous studies on the Ising and Potts models.¹⁶⁻²⁰

IV. CONCLUSION

Our investigation on the eight-state Potts model on the 2D quasiperiodic octagonal tiling has evidenced drastic free boundary effects in studying first-order transitions by MC simulations. These effects strongly disturb the probability distributions of the internal energy which do not exhibit two peaks in the vicinity of $T_c(L)$ as for systems with periodic boundary conditions. Rather than increasing the size of the tilings, an analysis of the energy probability distributions of the core of the tilings has been used to evidence a first-order transition, as in 2D periodic lattices. From MC data relative to the whole tilings, the L^2 behavior has not been observed, neither for C_{max} nor for χ_{max} , probably because of free boundary effects. Quite surprisingly, MC data for the core of the tilings reveal different scaling behavior for χ_{max} and C_{max} (L^2 behavior for χ_{max} and a nonanalytic form for C_{max}).

A generalized exact renormalization group (RG) equation for the Ginzburg–Landau–Wilson functional of an arbitrary symmetry, containing invariants of all orders, with nonlocal vertices is derived. Unlike other RG equations which contain an infinite number of redundant operators, the equation derived is free of them. © 1998 American Institute of Physics. [S0021-8979(98)32911-4]

The new concepts brought about by the renormalization group (RG) theory in the 1970s helped one to understand critical phenomena at continuous phase transitions in magnetic systems.¹ Using RG theory, systematic perturbative RG expansions were developed to calculate critical exponents with a high accuracy.^{2,3} In addition to the perturbation theory, RG has been successful in deriving exact RG equations,⁴ which not only provide a good insight of the theory, but also give a basis for developing new approximation schemes.^{5–9} Working with exact RG equations is a difficult task which has its origin in the fact that an exact RG equation contains an infinite number of redundant operators,^{10–12} which carry no physical meaning. Their exclusion from the RG equation is therefore a necessary but at the same time a complicated task, which requires imposing additional conditions. The problem of eliminating redundant operators for isotropic systems was considered in Ref. 8. In the present article we develop a new RG procedure applicable to arbitrary anisotropic systems. As a result we obtain an exact RG equation free of redundant operators.

We start with the most general kind of Ginzburg–Landau–Wilson functional

$$H_I[\varphi(\mathbf{q})] = \sum_{k=0}^{\infty} 2^{1-2k} \int_{q_1 \dots q_{2k}} \sum_{\alpha_1, \dots, \alpha_{2k}=1}^n \left[g_k^{\alpha_1, \dots, \alpha_{2k}} \times (\mathbf{q}_1, \dots, \mathbf{q}_{2k}) (2\pi)^d \delta \left(\sum_{i=1}^{2k} \mathbf{q}_i \right) \times \prod_{i=1}^{2k} \varphi^{\alpha_i}(\mathbf{q}_i) \right], \quad (1)$$

where φ is an n -component vector and $\int_{\mathbf{q}} \equiv \int d^d q / (2\pi)^d$. The vertices \hat{g}_k have an arbitrary tensorial structure with respect to the space indices α_i . Let us define an RG procedure in the following way. We cut off all momentum integrals at an upper momentum Λ by adding to the functional H_I a term H_0

$$H_0[\varphi] = \frac{1}{2} \int_{\mathbf{q}} G_0^{-1}(q, \Lambda) |\varphi(\mathbf{q})|^2, \quad (2)$$

where the propagator G_0 is defined by

$$G_0(q, \Lambda) = q^{-2} S(q^2/\Lambda^2). \quad (3)$$

Here $S(x)$ is a monotonic function with the properties $S(x=0)=1$ and $\lim_{x \rightarrow \infty} S(x)x^m = 0$ for any m .

We now perform two steps which are standard for RG. First, apply a Kadanoff transformation to thin out the original Hamiltonian by integrating those Fourier components $\varphi(\mathbf{q})$ corresponding to momenta within a spherical shell $\Lambda(1-\xi) < q < \Lambda$ in momentum space with $\xi \ll 1$. The Kadanoff transformation succeeds in bringing down the cut-off momentum to $\Lambda(1-\xi)$. Second, we rescale all the rest momenta in order to restore the original cutoff momentum Λ .

Let us introduce the designation:

$$Z = \int D\varphi \exp(-H[\varphi]) \\ = Z_0 \langle \exp(-H_I[\varphi]) \rangle_{0,\Lambda} \equiv Z_0 \langle w[\varphi] \rangle_{0,\Lambda}, \quad (4)$$

where

$$Z_0 = \int D\varphi \exp(-H_0[\varphi]), \quad (5)$$

and the averaging $\langle \dots \rangle_{0,\Lambda}$ is performed with respect to the functional $H_0[\varphi]$ at a given value of Λ . Note that if $\varphi(\mathbf{q}) = \varphi_1(\mathbf{q}) + \varphi_2(\mathbf{q})$ and $G_0(q, \Lambda) = G_{01}(q, \Lambda_1) + G_{02}(q, \Lambda_2)$, the following identity can be generated:

$$\langle w[\varphi] \rangle_{0,\Lambda} \equiv Z_0^{-1} \int D\varphi w[\varphi] \exp(-H_0[\varphi]) \\ = Z_{01}^{-1} Z_{02}^{-1} \int D\varphi_1 D\varphi_2 w[\varphi_1, \varphi_2] \\ \times \exp(-H_0[\varphi_1, \varphi_2]), \quad (6)$$

where

$$Z_{0i} = \int D\varphi_i \exp \left[-\frac{1}{2} \int_{\mathbf{q}} G_{0i}^{-1}(q, \Lambda_i) |\varphi_i(\mathbf{q})|^2 \right]; \\ H_{0i}[\varphi_1, \varphi_2] = \frac{1}{2} \int_{\mathbf{q}} G_{01}^{-1}(q, \Lambda_1) |\varphi_1(\mathbf{q})|^2 \\ + \frac{1}{2} \int_{\mathbf{q}} G_{02}^{-1}(q, \Lambda_2) |\varphi_2(\mathbf{q})|^2. \quad (7)$$

Choosing $G_{01}(q, \Lambda_1) = G_0(q, \Lambda(1 - \xi))$ with $\xi \ll 1$, makes the function G_{02} of order ξ ,

$$\begin{aligned} G_{02}(q, \Lambda_2) &= G_0(q, \Lambda) - G_{01}(q, \Lambda_1) \\ &\approx \xi \Lambda \frac{\partial G_0(q, \Lambda)}{\partial \Lambda} \equiv 2\xi h(q), \\ h(q) &= q^{-2} \Lambda^2 \frac{dS(q^2/\Lambda)}{d\Lambda^2}. \end{aligned} \quad (8)$$

Modes $\varphi_2(\mathbf{q})$ are those with momenta within a shell $\Lambda(1 - \xi) < q < \Lambda$ which should be integrated out. To do so and have the first step completed we expand $\langle w[\varphi_1, \varphi_2] \rangle$ in Eq. (6) with respect to $\varphi_2(\mathbf{q})$ to obtain

$$\begin{aligned} \langle w[\varphi] \rangle_{0,\Lambda} &= Z_{01}^{-1} Z_{02}^{-1} \int D\varphi_1 D\varphi_2 \left[w[\varphi_1] \right. \\ &\quad + \int_q \sum_\alpha \frac{\delta w[\varphi_1]}{\delta \varphi_1^\alpha(\mathbf{q})} \varphi_2^\alpha(\mathbf{q}) \\ &\quad + \frac{1}{2} \int_{qq'} \sum_{\alpha,\beta} \frac{\delta^2 w[\varphi_1]}{\delta \varphi_1^\alpha(\mathbf{q}) \delta \varphi_1^\beta(\mathbf{q}')} \\ &\quad \left. \times \varphi_2^\alpha(\mathbf{q}) \varphi_2^\beta(\mathbf{q}') + \dots \right] \exp(-H_0[\varphi_1, \varphi_2]). \end{aligned} \quad (9)$$

Having in mind the Gaussian nature of $H_0[\varphi_1, \varphi_2]$ only even terms in the above expansion survive. Keeping terms of the lowest order with respect to ξ the integration yields

$$\begin{aligned} \langle w[\varphi(\mathbf{q})] \rangle_{0,\Lambda} &\approx \left\langle \left(1 + \xi V \int_q h(q) \sum_\alpha \frac{\delta^2}{\delta \varphi^\alpha(\mathbf{q}) \delta \varphi^\alpha(-\mathbf{q})} \right) \right. \\ &\quad \left. \times w[\varphi(\mathbf{q})] \right\rangle_{0,\Lambda(1-\xi)}, \end{aligned} \quad (10)$$

where the averaging $\langle \dots \rangle_{0,\Lambda(1-\xi)}$ is performed with respect to the functional

$$H_0[\varphi, \Lambda(1 - \xi)] = \frac{1}{2} \int_q G_0^{-1}(q, \Lambda(1 - \xi)) |\varphi(\mathbf{q})|^2. \quad (11)$$

Consequently, the right-hand side of Eq. (10) contains effectively only modes with $q < \Lambda(1 - \xi)$. The first step of the RG transformation has been completed.

For the second step, we must rescale the momentum to restore the original cutoff Λ through transformation $\mathbf{q} = \mathbf{q}'(1 - \xi)$. This rescaling changes $H_0[\Lambda]$ to $H_0[\Lambda(1 - \xi)]$ as follows:

$$\begin{aligned} H_0[\varphi, \Lambda(1 - \xi)] &= \frac{1}{2} \int_q G_0^{-1}(q, \Lambda(1 - \xi)) |\varphi(\mathbf{q})|^2, \\ H_0'[\varphi, \Lambda] &= \frac{(1 - \xi)^{d+2}}{2} \int_q G_0^{-1}(q, \Lambda) |\varphi[\mathbf{q}(1 - \xi)]|^2. \end{aligned} \quad (12)$$

However, we must restore this change since it is essential to the restoration of Λ . We do so by substituting $\varphi(\mathbf{q})$,

$$\begin{aligned} \varphi^\alpha(\mathbf{q}) &= \sum_\beta [\delta^{\alpha\beta} + \xi \epsilon^{\alpha\beta}(\mathbf{q})] \varphi'^\beta[\mathbf{q}(1 + \xi)] \\ &= \sum_\beta \left[\delta^{\alpha\beta} + \xi \left(\epsilon^{\alpha\beta}(\mathbf{q}) + \delta^{\alpha\beta} \mathbf{q} \cdot \frac{\partial}{\partial \mathbf{q}} \right) \right] \varphi'^\beta(\mathbf{q}), \end{aligned} \quad (13)$$

where at present $\epsilon^{\alpha\beta}(\mathbf{q})$ is an arbitrary tensor with the only condition $\epsilon^{\alpha\beta}(\mathbf{q}) = \epsilon^{\beta\alpha}(-\mathbf{q})$. Then we apply the above transformation to $\langle w[\varphi(\mathbf{q})] \rangle_{0,\Lambda(1-\xi)}$ of Eq. (10). After keeping terms of the lowest order in ξ and using the relationship $w[\varphi] = \exp(-H_L[\varphi])$ we derive the RG equation for H_L ,

$$\begin{aligned} \dot{H}_L[\varphi] &= Vd \frac{\partial H_L[\varphi]}{\partial V} + \frac{V}{2} \int_q \sum_\alpha \eta^{\alpha\alpha}(\mathbf{q}) \\ &\quad - \frac{1}{2} \int_{q,\alpha,\beta} \eta^{\alpha\beta}(\mathbf{q}) G_0^{-1}(q, \Lambda) \varphi^\alpha(\mathbf{q}) \varphi^\beta(-\mathbf{q}) \\ &\quad + \int_{q,\alpha,\beta} \left[\left(\frac{d+2}{2} \delta^{\alpha\beta} - \frac{\eta^{\alpha\beta}(\mathbf{q})}{2} \right) \varphi^\alpha(\mathbf{q}) + \delta^{\alpha\beta} \mathbf{q} \cdot \frac{\partial \varphi^\alpha(\mathbf{q})}{\partial \mathbf{q}} \right] \frac{\delta H_L[\varphi]}{\delta \varphi^\beta(\mathbf{q})} + \int_q h(q) \\ &\quad \times \sum_\alpha \left[\frac{\delta^2 H_L[\varphi]}{\delta \varphi^\alpha(\mathbf{q}) \delta \varphi^\alpha(-\mathbf{q})} - \frac{\delta H_L[\varphi]}{\delta \varphi^\alpha(\mathbf{q})} \frac{\delta H_L[\varphi]}{\delta \varphi^\alpha(-\mathbf{q})} \right]. \end{aligned} \quad (14)$$

Here $\eta^{\alpha\beta}(\mathbf{q})$ is defined as

$$\eta^{\alpha\beta}(\mathbf{q}) = \delta^{\alpha\beta}(d+2) - 2\epsilon^{\alpha\beta}(-\mathbf{q}). \quad (15)$$

Equation (14) is an exact RG equation for functional (1). It contains an arbitrary function $\eta^{\alpha\beta}(\mathbf{q})$. Note that if we choose $\eta^{\alpha\beta}(\mathbf{q}) = 0$ then the resulting simplified RG equation will be similar to the traditional ones, and as in those cases it will contain redundant operators. Not being physical, these operators must be eliminated by developing a proper procedure. Our goal is to find the correct choice of the tensor $\eta^{\alpha\beta}$ which will make the RG Eq. (14) free of redundant operators. Explicitly, Eq. (14) generates different vertices $g_k^{\alpha\beta}(\mathbf{q})$. Some of the q -dependent part of this renormalization can be incorporated into G_0 of the functional H_0 . This means that the cutoff Λ is affected which should, however, remain unchanged. To avoid so, we define $\eta^{\alpha\beta}(\mathbf{q})$ such that it cancels out the q -dependent renormalization of the vertex $g_1^{\alpha\beta}(\mathbf{q})$. To achieve this, we use Eq. (14) to write explicitly the change of vertices $g_1^{\alpha\beta}$ corresponding to zeroth and first order in $\varphi^\alpha(\mathbf{q}) \varphi^\beta(-\mathbf{q})$. Then we require that $g_1^{\alpha\beta}$ is momentum independent initially and must remain so after the transformation so that H_0 which controls the cutoff remains intact. This requirement finds a momentum dependent expression for the tensor $\eta^{\alpha\beta}(\mathbf{q})$. First, we extract an explicit equation for the vertex $g_1(\mathbf{q})$ from Eq. (14),

$$\begin{aligned} \dot{g}_1^{\alpha\beta}(\mathbf{q}) = & -\eta^{\alpha\beta}(q)G_0^{-1}(q, \Lambda) + \sum_{\gamma} \left[2\delta^{\alpha\gamma} - \eta^{\alpha\gamma}(\mathbf{q}) \right. \\ & \left. - \delta^{\alpha\gamma} \mathbf{q} \cdot \frac{\partial}{\partial \mathbf{q}} \right] g_1^{\gamma\beta}(\mathbf{q}) + \sum_{\gamma} Q^{\alpha\beta\gamma\gamma}(\mathbf{q}) \\ & - 2 \sum_{\gamma} g_1^{\alpha\gamma}(\mathbf{q}) g_1^{\gamma\beta}(\mathbf{q}) h(q), \end{aligned} \quad (16)$$

where

$$Q^{\alpha\beta\gamma\delta}(\mathbf{q}) = 3 \int_p h(p) g_2^{\alpha\beta\gamma\delta}(\mathbf{q} - \mathbf{q}, \mathbf{p}, -\mathbf{p}). \quad (17)$$

We can now split Eq. (16) into two equations: one for \hat{g}_{10} , which is the momentum independent part of $\hat{g}_1(\mathbf{q})$, and another for $\hat{g}'_1(\mathbf{q}) = \hat{g}_1(\mathbf{q}) - \hat{g}_{10}$,

$$\begin{aligned} \dot{g}_{10}^{\alpha\beta} = & \sum_{\gamma} [2\delta^{\alpha\gamma} - \eta^{\alpha\gamma}(0)] g_{10}^{\gamma\beta} + \sum_{\gamma} Q^{\alpha\beta\gamma\gamma}(0) \\ & - 2 \sum_{\gamma} g_{10}^{\alpha\gamma} g_{10}^{\gamma\beta} h(0); \end{aligned} \quad (18)$$

$$\begin{aligned} \dot{g}'_1{}^{\alpha\beta}(\mathbf{q}) = & -\eta^{\alpha\beta}(\mathbf{q})G_0^{-1}(q, \Lambda) + \sum_{\gamma} \left\{ \left[2\delta^{\alpha\gamma} - \eta^{\alpha\gamma}(\mathbf{q}) \right. \right. \\ & \left. - \delta^{\alpha\gamma} \mathbf{q} \cdot \frac{\partial}{\partial \mathbf{q}} \right] g_1^{\gamma\beta}(\mathbf{q}) - [\eta^{\alpha\gamma}(\mathbf{q}) - \eta^{\alpha\gamma}(0)] g_{10}^{\gamma\beta} \\ & + Q^{\alpha\beta\gamma\gamma}(\mathbf{q}) - Q^{\alpha\beta\gamma\gamma}(0) - 2g_{10}^{\alpha\gamma} g_{10}^{\gamma\beta} [h(q) \\ & - h(0)] - 2[g_{10}^{\alpha\gamma} g_1^{\gamma\beta}(\mathbf{q}) + g_1^{\alpha\gamma}(\mathbf{q}) g_{10}^{\gamma\beta} \\ & \left. + g_1^{\alpha\gamma}(\mathbf{q}) g_1^{\gamma\beta}(\mathbf{q})] h(q) \right\}. \end{aligned} \quad (19)$$

Using Eq. (19) we can define the function $\eta^{\alpha\beta}(\mathbf{q})$ such that the derivative of $\hat{g}'_1(\mathbf{q})$ is equal to zero. This means that if the vertex $\hat{g}_1(\mathbf{q})$ of the initial functional H_I is a constant then a q -dependent part of this vertex will not be generated and the functional H_0 will be intact within the renormalization procedure. The requirement $\hat{g}'_1(\mathbf{q}) = 0$ implies that

$$\begin{aligned} \eta^{\alpha\beta}(\mathbf{q}) = & \eta^{\alpha\beta}(0) - \sum_{\nu} \left\{ \eta^{\alpha\nu}(0) G_0^{-1}(q, \Lambda) \right. \\ & + \sum_{\gamma} [2[h(q) - h(0)] g_{10}^{\alpha\gamma} g_{10}^{\gamma\nu} - Q^{\alpha\nu\gamma\gamma}(\mathbf{q}) \\ & \left. + Q^{\alpha\nu\gamma\gamma}(0)] \right\} [g_{10}^{\nu\beta} + G_0^{-1}(q, \Lambda) \delta^{\nu\beta}]^{-1}. \end{aligned} \quad (20)$$

Equation (20) defines the momentum dependent part of the function $\eta^{\alpha\beta}(\mathbf{q})$. We still have to define n^2 components of the tensor $\eta^{\alpha\beta}(0)$. We can use these values to simplify the RG equation and clarify the physical meaning of $\eta^{\alpha\beta}$. To do this, let us diagonalize the vertex \hat{g}_{10} in the initial functional H_1 . This can always be done without loss of generality. The diagonal components of this tensor are trial critical

temperatures for the corresponding components of the order parameter $\varphi(\mathbf{q})$. However, as one can see from Eq. (18), even if the nondiagonal part of the tensor $g_{10}^{\alpha\beta}$ does not exist in the initial functional, it will be generated within the renormalization process. We can use the arbitrariness of tensor $\eta^{\alpha\beta}$ to keep the tensor $g_{10}^{\alpha\beta}$ diagonal. In order to do this, let us split Eq. (18) into two separate equations, for diagonal and nondiagonal parts of the vertex $g_{10}^{\alpha\beta}$. Defining $g_{10}^{\alpha\beta} = \delta^{\alpha\beta} r^{\alpha} + (1 - \delta^{\alpha\beta}) r^{\alpha\beta}$, we have

$$r^{\alpha} = (2 - \eta^{\alpha}) r^{\alpha} + Q^{\alpha}(0) - 2(r^{\alpha})^2 h(0); \quad (21)$$

$$\begin{aligned} r^{\alpha\beta} = & (2 - \eta^{\alpha}) r^{\alpha\beta} - \sum_{\gamma} \tilde{\eta}^{\alpha\gamma} r^{\gamma\beta} + \tilde{Q}^{\alpha\beta}(0) - \tilde{\eta}^{\alpha\beta} r^{\beta} \\ & - 2 \left[r^{\alpha} r^{\alpha\beta} + r^{\alpha\beta} r^{\beta} + \sum_{\gamma} r^{\alpha\gamma} r^{\gamma\beta} \right] h(0), \end{aligned} \quad (22)$$

where η^{α} , Q^{α} and $\tilde{\eta}^{\alpha\beta}$, $\tilde{Q}^{\alpha\beta}$ are diagonal and nondiagonal elements of tensors $\eta^{\alpha\beta}$ and $\sum_{\gamma} Q^{\alpha\beta\gamma\gamma}$, respectively,

$$\begin{aligned} \eta^{\alpha\beta}(0) = & \delta^{\alpha\beta} \eta^{\alpha} + (1 - \delta^{\alpha\beta}) \tilde{\eta}^{\alpha\beta}; \\ \sum_{\gamma} Q^{\alpha\beta\gamma\gamma}(\mathbf{q}) = & \delta^{\alpha\beta} Q^{\alpha}(\mathbf{q}) + (1 - \delta^{\alpha\beta}) \tilde{Q}^{\alpha\beta}(\mathbf{q}). \end{aligned} \quad (23)$$

Now by choosing

$$\tilde{\eta}^{\alpha\beta} = \tilde{Q}^{\alpha\beta} / r^{\beta}, \quad (24)$$

it is guaranteed that if the initial functional does not contain nondiagonal parts of the vertex \hat{g}_1 , then this vertex remains diagonal after the renormalization. If at last we require that the expansion of $\eta^{\alpha\beta}(\mathbf{q})$ does not contain q^2 terms, then the diagonal part of the tensor $\eta^{\alpha\beta}(0)$ is

$$\eta^{\alpha} = \frac{d}{dq^2} [Q^{\alpha}(\mathbf{q}) - 2h(q)(r^{\alpha})^2]_{q=0}. \quad (25)$$

Function $\eta^{\alpha\beta}(\mathbf{q})$ is now completely defined and there is no more freedom in the exact RG Eq. (14), therefore it must contain no redundant operators. The physical meaning of the function $\eta^{\alpha\beta}$ is suggested by Eq. (21): at the stable fixed point of the functional (1), η^{α} is equal to the critical exponent η of the corresponding critical mode φ^{α} .

Random-exchange and random-field Ising model-like behaviors in $\text{Fe}_{0.48}\text{Zn}_{0.52}\text{F}_2$

By using a local mean-field microscopical numerical approach, we investigate the role of frustration, random vacancies, and magnetic field cycles on the random-exchange and random-field Ising model-like behaviors of the diluted antiferromagnet $\text{Fe}_{0.48}\text{Zn}_{0.52}\text{F}_2$. The analysis includes studies on microscopic configurations, distribution of local effective fields, and the crossover exponent ϕ , which were found to be in good agreement with the experimental results. © 1998 American Institute of Physics. [S0021-8979(98)23211-7]

Much progress has been achieved¹ in the last few years on the characterization of the phase diagram of the insulating diluted antiferromagnet (DAF) $\text{Fe}_x\text{Zn}_{1-x}\text{F}_2$. Nevertheless, a complete understanding of the relative influence of its microscopic ingredients, namely, the local density fluctuations, the presence of a small magnetic frustration, and the short range of the spin interactions, is still lacking. In the following, we investigate the roles of these elements in the presence of magnetic field cycles by using a local mean field (LMF) microscopical numerical approach.^{2,3}

The DAF compound $\text{Fe}_x\text{Zn}_{1-x}\text{F}_2$ has a strong single-ion anisotropy in the easy-magnetization direction which makes it a nearly ideal experimental realization of an Ising system.⁴ All its important microscopic ingredients can be found in the DAF Hamiltonian in the presence of a uniform magnetic field H ,

$$\mathcal{H} = \sum_{\langle i, \delta_l \rangle} J_l \mathcal{E}_i \mathcal{E}_{i+\delta_l} S_i S_{i+\delta_l} - \mu_0 \sum_i \mathcal{E}_i S_i H, \quad (1)$$

where $S_i = \pm 2$ (Fe^{+2}), $\mathcal{E}_i = 0, 1$, and l is summed over the three short-range exchange interactions between nearest neighbors in a centered tetragonal lattice. By fitting the Néel temperature which marks the onset of the AF phase for the pure system, $T_N(x=1) \approx 78$ K, we fixed the exchange constants so that the experimental ratios $j_1 = J_1/J_2 = -0.013$ and $j_3 = J_3/J_2 = +0.053$ measured for the pure compound FeF_2 are kept unaltered.⁴ Disorder and frustration are present respectively in the form of local density fluctuations due to the random quenched substitution of magnetic ions Fe^{+2} by nonmagnetic ones Zn^{+2} ("vacancy" sites), and in the presence of a small frustrated super-exchange planar interaction j_3 with respect to the dominant AF coupling j_2 .

The LMF method^{2,3} consists in solving iteratively the self-consistent equations involving the thermally averaged spins, $m_i \in [-2, 2]$,

$$m_i = \langle S_i \rangle_T = 2 \tanh\{h_i / K_B T\}, \quad \mathcal{E}_i = 1, \quad (2)$$

where the local field effectively seen by this spin is

$$h_i = - \sum_{\delta_l} J_{i+\delta_l} \mathcal{E}_{i+\delta_l} m_{i+\delta_l} + \mu_0 H. \quad (3)$$

The numerical procedure starts by choosing an initial random configuration $\{S_i, \mathcal{E}_i\}$ in the high-temperature ($T = 150$ K) paramagnetic (PM) phase. The system is then cooled in a rate $\Delta T = 0.05$ K and, at each temperature, Eqs. (2) and (3) are iterated for every magnetic site until a convergence criterium^{2,3} is satisfied. The cooling procedure is repeated until reaching the minimum temperature $T = 2$ K from which the system is heated by using the same amount ΔT , and then the measurements are done. We have followed the experimental procedures in $\text{Fe}_x\text{Zn}_{1-x}\text{F}_2$ as close as possible. In a zero-field cycle (ZFC) the system is cooled in $H = 0$ to the minimum temperature and a magnetic field is applied along the heating process. On the other hand, in a field cycle (FC) both cooling and heating procedures are performed in the presence of H . We simulate bcc lattices with two sublattices of 30^3 sites each and periodic boundary conditions. In order to eliminate any possible dependence of the results on some initial configuration, we average over 50 independent samples $\{S_i, \mathcal{E}_i\}$.

The compound $\text{Fe}_{0.48}\text{Zn}_{0.52}\text{F}_2$ presents a random-exchange Ising model (REIM)-like behavior at zero field.^{1,5} In $H \neq 0$, it experiences^{1,5} a field-induced crossover upon ZFC from the REIM to the random-field Ising model (RFIM)-like behavior. The LMF results indicate⁶ that the combined action of random vacancies and magnetic field induces an AF long-range order (LRO) that exist up to the neighborhood of the critical temperature, and is essentially constituted by two large slightly-interacting interpenetrating structures with AF internal arrangements, each one occupying approximately half of the sample, in agreement with some very recent experiments.^{1,7} The domain walls are strongly pinned along the vacancies⁸ and can minimize the energy cost by avoiding as much as possible to embody frustrated magnetic bonds so that a different picture emerges

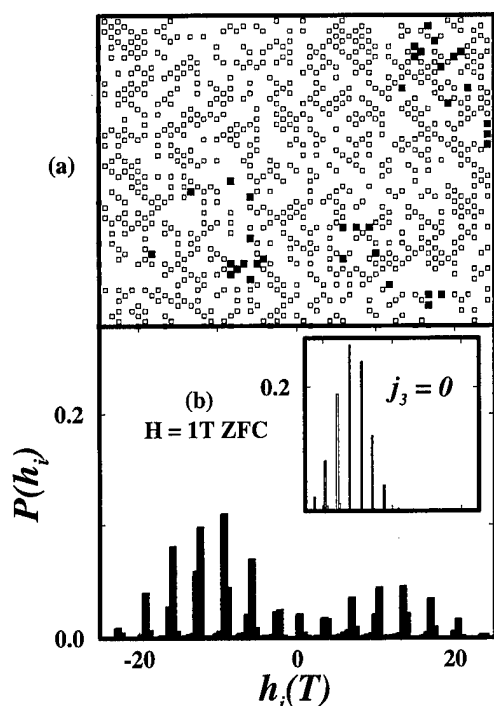

FIG. 1. (a) Few isolated clusters (full squares) represent spins reversed by a ZFC magnetic field, $H=1$ T, with respect to the $H=0$ frustrated configuration close to the ground state, $T/T_N(x=1)=0.06$. Odd (even) horizontal lines correspond to consecutive layers of sublattice A (B). (b) Correspondent local effective field distribution $P(h_i)$ of one sublattice. The nonfrustrated case is presented in the inset.

with respect to the usual Imry–Ma argument,⁹ including the existence of fractal domains.¹⁰

The microscopic states for low and moderate ZFC fields are similar to those obtained in $H=0$, except for the presence of some small isolated clusters, as also experimentally probed.^{1,7} In Fig. 1(a), two consecutive layers (one of each sublattice) randomly chosen in the bulk of the system are projected onto a plane so that spins belonging to the sublattice A (B) are displayed by squares in the odd (even) horizontal lines. Full squares represent reversed spins in the frustrated systems after $H=1$ T ZFC, relative to the $H=0$ case at the very proximity of the ground state, $T/T_N(x=1)=0.06$. Figure 2(a) displays the associated field distributions for one sublattice of these samples, with the nonfrustrated case shown in the inset. A very similar picture is also found in $H=0$. Furthermore, we notice that frustration plays an important role for the nucleation process upon ZFC by inducing the presence of competitive local fields. Indeed, the presence of frustration introduces more important changes on the properties of the system than low and moderate magnetic fields do after ZFC.

On the other hand, a FC procedure at $x=0.48$ leads to a very distinct domain state without AF LRO at low temperatures even for low fields.¹⁰ In Fig. 1(b), a very small field $H=1$ G was applied upon FC and the differences with respect to the zero-field configuration at $T/T_N(x=1)=0.06$ are represented by full squares. Figure 2(b) displays the associated field distributions for one sublattice. Notice from Fig. 2(b) that frustration is unimportant in the FC regime.

The field-induced crossover upon ZFC from the REIM

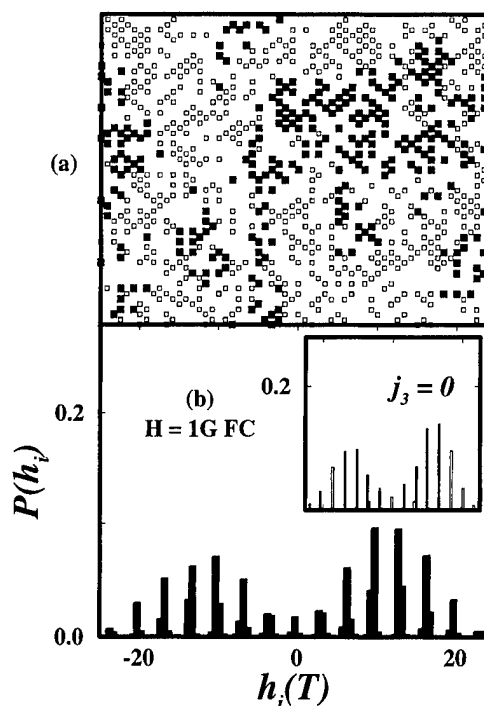

FIG. 2. (a) Even a very low magnetic field $H=1$ G upon FC induces a remarkably distinct low- T configuration (differences indicated by full squares) relative to the AF LRO $H=0$ and ZFC states. The correspondent local effective field distributions of one sublattice are depicted in (b) for the frustrated and nonfrustrated (inset) cases.

to the RFIM-like behavior is described by the crossover exponent ϕ ,¹¹

$$T^* - T_i(H) = AH^{2/\phi}. \quad (4)$$

Above, the same scaling dependence experimentally¹¹ and numerically¹⁰ seen for the critical $[T_c(H)]$ and equilibrium $[T_{eq}(H)]$ lines is accounted by considering both cases, $T_i(H)=T_c(H)$ and $T_i(H)=T_{eq}(H)$. In the former, $T^*=T_N(x=0.48)$, whereas in the latter T^* is the highest temperature below which the total magnetizations measured after ZFC and FC begin to differ. The LMF results for the exponents in the presence of frustration, $\phi_c=1.28\pm0.06$ and $\phi_{eq}=1.30\pm0.08$, nearly agree with the experimental¹¹ and Monte Carlo¹⁰ ones, $\phi\approx1.40$ – 1.46 , if the range of concordance between independent measurements is considered. Notice that the equivalent scaling dependence in the critical and equilibrium lines is also probed by the LMF method. It is remarkable that the exponents do not depend (within the error bars) on the presence of frustration for both $T_{eq}(H)$ and $T_c(H)$ lines. Figure 3 displays the numerical data along with the best-fitting curves and the most generally accepted experimental value, $\phi=1.42$.^{1,11} The LMF approach causes an enlargement of the region where the $T_{eq}(H)$ and $T_c(H)$ lines differ. We have also observed a reentrant behavior in $T_{eq}(H)$ for extremely low fields, $H<0.01$ T, as detailed in the inset of Fig. 3(b). However, the absence of experimental data in this range of fields prevent us to comment on the reality of this reentrance. It would be interesting to probe it in the real compound.

From the H vs T diagrams one can also speculate about the irreversibility and stability of the AF LRO at $x=0.48$. In

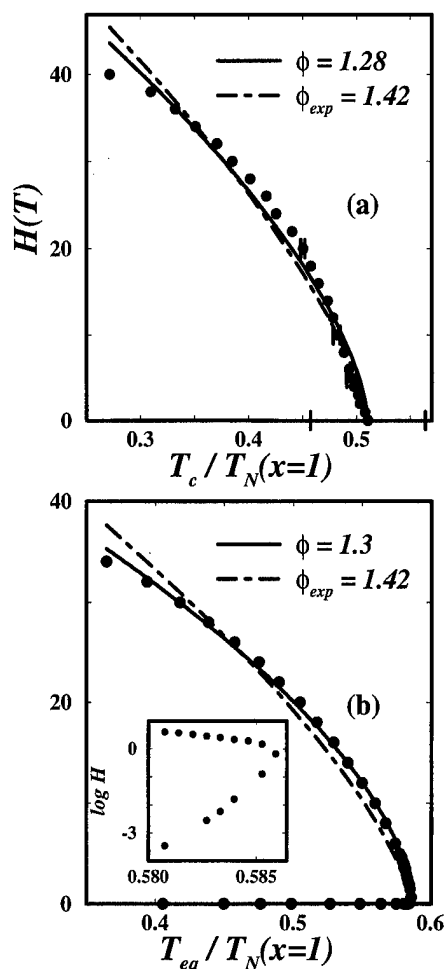

FIG. 3. (a) Critical and (b) equilibrium lines at $x=0.48$. The respective best-fitting plots $\phi=1.28$ and $\phi=1.3$ are shown along with the experimental value $\phi=1.42$ (see Ref. 1) characteristic of the RFIM-like behavior. Inset in (b) displays the numerical reentrance observed for very low magnetic fields, $H \leq 0.1$ T.

the free energy surface, irreversibility is related to the displacement or disappearance of local minima due to changes in H or T .² After ZFC to a low-temperature state, when the uniform magnetic field is turned on and kept fixed, the system initially exhibits an irreversible AF phase whose LRO is broken down when the critical line $T_c(H)$ is crossed during the heating process. The system thus enters an irreversible close-PM regime in which spin correlations still exist.⁶ Below $T_c(H)$ the difference between the ZFC and FC measures means that the FC domain state cannot reach its equilibrium configuration within the characteristic LMF or experimental times. In this sense only the ZFC states are quasi-

equilibrated. On the contrary, in the vitreous intermediate phase, $T_c(H) < T < T_{eq}(H)$, it has been shown² that the domain-like states without fully developed AF LRO have less free energy than those ones associated with the AF LRO. The high- T reversible behavior is restored only after crossing the $T_{eq}(H)$ line above which the equilibrium measurements from both ZFC and FC procedures coincide.

Finally, we would like to mention that the consistency of the LMF results was also attested by applying the same numerical procedure for the system at $x=0.25$. The value obtained,¹² $\phi_{eq}=3.8 \pm 0.6$, is in good agreement with the experimental one, $\phi=3.4 \pm 0.2$, measured¹ for $\text{Fe}_{0.25}\text{Zn}_{0.75}\text{F}_2$, which is associated with the presence of a spin-glass-like phase without AF LRO. The independence of frustration in the crossover exponents has been also observed.¹²

In the crystal structures of $\text{CsFe}(\text{SO}_4)_2$, $\text{RbFe}(\text{SO}_4)_2$, and $\text{KFe}(\text{SO}_4)_2$, the magnetic Fe^{3+} ions form a triangular array in well separated layers. $\text{CsFe}(\text{SO}_4)_2$ and $\text{RbFe}(\text{SO}_4)_2$ may be regarded as realizations of the highly frustrated triangular lattice antiferromagnet, whereas $\text{KFe}(\text{SO}_4)_2$ is a suspected realization of the row model. The latter model is characterized by two couplings J' and J , and for $J'/J > 0.5$ forms a helical spin structure with an incommensurate repeat distance. The regular triangular lattice magnet may be described by the row model with $J' = J$, and its “120°” spin structure may be regarded as a special case of this helical structure. We have determined the low temperature (1.3 K) magnetic structures adopted by $\text{CsFe}(\text{SO}_4)_2$, $\text{RbFe}(\text{SO}_4)_2$, and $\text{KFe}(\text{SO}_4)_2$ by powder neutron diffraction. $\text{CsFe}(\text{SO}_4)_2$ and $\text{RbFe}(\text{SO}_4)_2$ adopt the expected 120° helical spin structure of the triangular lattice magnet, but $\text{KFe}(\text{SO}_4)_2$ does not adopt the expected incommensurate helical structure of the row model. Rather, it adopts a sine wave modulated structure. Possible reasons for this behavior are discussed. © 1998 American Institute of Physics. [S0021-8979(98)50511-7]

The triangular lattice antiferromagnet¹ is the prototypical two-dimensional frustrated magnet. It exhibits a wealth of unusual properties, such as novel critical exponents,² large quantum fluctuation effects,³ and anomalous percolation properties.⁴ Recently we showed that the materials with layered crystal structures related to that of the mineral Yavapaiite $\text{KFe}(\text{SO}_4)_2$ are of interest as realizations of a model quasi-two-dimensional triangular lattice antiferromagnet.⁵ With regard to their magnetic properties, the Yavapaiite materials can be classified into two major groups, depending on the symmetry of the triangular net occupied by the magnetic atoms. The materials in the first group, which includes $\text{CsFe}(\text{SO}_4)_2$ and $\text{RbFe}(\text{SO}_4)_2$, have an equilateral triangular lattice, and approximate very well to the two-dimensional Heisenberg model antiferromagnet on the triangular lattice. Those in the second group, which includes $\text{KFe}(\text{SO}_4)_2$, have an isosceles triangular (i.e., centered rectangular) lattice. They may thus be considered realizations of the “row” model.^{6–8} The relationship between the regular triangular lattice model and the row model is illustrated in Fig. 1; in the regular triangular lattice model all magnetic bonds are of the same strength (J), whereas in the row model “horizontal”

bonds are of different strength (J') to the remaining bonds (J). Zhang *et al.*⁶ and Kawamura⁷ have studied the XY row model and shown that for $J'/J > 1/2$ the ground state is a spin helix propagating along the row direction, with period determined by the ratio J'/J . The regular triangular lattice, with $J'/J = 1$, may be regarded as a special case of the row model, in which the turn angle of the helix is 120°; however, for general J'/J , the period of the helix is incommensurate with the lattice. The stacked row model, with unfrustrated interlayer coupling, was introduced by Kawamura⁷ to explain the magnetic structure of RbMnBr_3 .⁹ However, the model can potentially be used to describe any C -centered spin lattice in which $a \approx b\sqrt{3}$. Thus, the class of C -centered orthorhombic compounds MXO_4 , such as MnSO_4 ¹⁰ and $\beta\text{-CrPO}_4$,¹¹ may also be regarded as realizations of this system; they indeed exhibit the expected incommensurate helical structure.

In this work we determine the low temperature magnetic structures adopted by the title compounds, and compare these with theoretical expectations for the row and triangular models. The magnetic susceptibility versus temperature curves of all three compounds show anomalies in the region of 4–5 K,⁵ which can be attributed to magnetic ordering transitions. Using the *D1B* powder diffractometer at the Institut Max von Laue—Paul Langevin, Grenoble, France, we

FIG. 1. (a) The regular (equilateral) triangular lattice, showing a unit cell (shaded area with vectors \mathbf{a} and \mathbf{b}); (b) the row model lattice, in which horizontal bonds (double lines) have a different strength to other bonds (single lines). In the crystal structures of $\text{CsFe}(\text{SO}_4)_2$ and $\text{RbFe}(\text{SO}_4)_2$ the magnetic Fe ions occupy a lattice of the type shown in (a), whereas in the crystal structure of $\text{KFe}(\text{SO}_4)_2$ the magnetic Fe atoms occupy a lattice of the type shown in (b). In (b) the primitive unit cell shown (shaded area with vectors \mathbf{a} and \mathbf{b}) describes the magnetic structure of $\text{KFe}(\text{SO}_4)_2$. The lattice sites labeled O , A , and B are referred to in the text.

have measured diffraction patterns both above ordering transition¹² and at 1.3 K, and subtracted these to create a magnetic-only diffraction pattern (in this temperature range thermal effects on the nuclear diffraction pattern are negligible). All the magnetic diffraction patterns show Bragg peaks arising from three-dimensional magnetic order. Magnetic structures were determined using the GSAS¹³ and FULLPROF¹⁴ program packages, assuming a pseudo-Voigt line shape, and zero point corrections and scale factors derived from fits to the nuclear structure. The magnetic form factor for Fe^{3+} was calculated from Ref. 15.

Crystallographic data for the three title compounds are given in Table I. In the case of $\text{CsFe}(\text{SO}_4)_2$ and $\text{RbFe}(\text{SO}_4)_2$, the magnetic diffraction pattern was indexed on a unit cell with $a_m = b_m = a\sqrt{3}$, $c_m = 2c$, $\alpha_m = \beta_m = 90^\circ$, $\gamma_m = 60^\circ$,

TABLE I. Crystallographic data for $\text{CsFe}(\text{SO}_4)_2$, $\text{RbFe}(\text{SO}_4)_2$, and $\text{KFe}(\text{SO}_4)_2$. The magnetic Fe^{3+} ions occupy the (0,0,0) position in each case, and so the Fe sublattice is uniquely defined by the centering symbol (P or C) of the space group. For full crystallographic details see Ref. 5.

Compound	Space group	Lattice parameters
$\text{CsFe}(\text{SO}_4)_2$	$P\bar{3}$	$a = b = 4.8612(5) \text{ \AA}$, $c = 8.7081(1) \text{ \AA}$ (20 K)
$\text{RbFe}(\text{SO}_4)_2$	$P\bar{3}$	$a = b = 4.8189(5) \text{ \AA}$, $c = 8.2248(2) \text{ \AA}$ (8 K)
$\text{KFe}(\text{SO}_4)_2$	$C2/m$	$a = 8.0926(8) \text{ \AA}$, $b = 5.1401(5) \text{ \AA}$, $c = 7.8026 \text{ \AA}$, $\beta = 95.155(11)^\circ$ (15 K)

FIG. 2. Fit of the magnetic model described in the text to the experimental magnetic-only powder diffraction pattern of $\text{CsFe}(\text{SO}_4)_2$ at 1.3 K. The figures show experimental (+ marks), calculated (upper solid line), and difference (observed—calculated, lower solid line) magnetic diffraction profiles.

where a , b , and c denote the crystallographic unit cell parameters. The diffraction data are well described by a model in which the spins form a three sublattice “120°” structure in the basal (ab) plane, and there are two basal planes per magnetic unit cell. Spins in adjacent layers are rotated by an angle ϕ , which was found to have the value $180^\circ \pm 10^\circ$ for $\text{CsFe}(\text{SO}_4)_2$ and $150^\circ \pm 10^\circ$ for $\text{RbFe}(\text{SO}_4)_2$. Note that powder neutron diffraction cannot give the in-plane spin direction for the high symmetry structures of $\text{CsFe}(\text{SO}_4)_2$ and $\text{RbFe}(\text{SO}_4)_2$.¹⁶ The refined values of the magnetic moments were $\mu = 4.2 \pm 0.2 \mu_B$ for $\text{CsFe}(\text{SO}_4)_2$ and $\mu = 4.5 \pm 0.2 \mu_B$ for $\text{RbFe}(\text{SO}_4)_2$, which are close to the maximum expected value $\mu = 5 \mu_B$ for Fe^{3+} . The fit to the experimental magnetic diffraction pattern for $\text{CsFe}(\text{SO}_4)_2$ is shown in Fig. 2.

In the case of $\text{KFe}(\text{SO}_4)_2$, the magnetic Bragg peaks could be indexed on the unit cell illustrated in Fig. 1(b). This cell is primitive in the basal ab plane, but contains two basal planes along the c axis.

With respect to this unit cell, the magnetic Bragg peaks could all be indexed by the wave vector $(0.73, -0.73, 0)$. This implies that neighboring spins along the row direction are approximately antialigned, but that the antiferromagnetic

FIG. 3. Sine-wave modulated magnetic structure used to describe the magnetic diffraction pattern of $\text{KFe}(\text{SO}_4)_2$, as described in the text. The figure shows two “rows” in the ab plane of the $\text{KFe}(\text{SO}_4)_2$ structure (not drawn to scale), with the projection of the magnetic structure into the ab plane. The spins shown lie along the $[1, 1, 1/2]$ and $[-1, -1, -1/2]$ directions, which are denoted as (+) or (−) on the diagram. The spin amplitude is modulated along $[1, -1, 0]$ (indices refer to the unit cell shown in Fig. 1). Note that the spins in the upper row may look more strongly modulated than those in the lower row, but in fact the modulation is the same. In the adjacent layer the spins similarly lie along either $[1, 1, -1/2]$ or $[-1, -1, 1/2]$.

FIG. 4. Fit of the magnetic model described in the text and shown in Fig. 3 to the experimental magnetic-only powder diffraction pattern of $\text{KFe}(\text{SO}_4)_2$ at 1.3 K. The figures show experimental (+ marks), calculated (upper solid line), and difference (observed—calculated, lower solid line) magnetic diffraction profiles.

rows are modulated with a long repeat distance which is incommensurate with the crystal structure (ratio of periodicities approximately equal to 0.73). The modulation may be of the sine wave or helical type, but the indexing imposes severe limitations on the possible magnetic models. All plausible models were tested. Helical structures were tested first, and it was found that none of these described the data, even assuming an elliptical, rather than circular, helix (and thereby introducing an extra fitting parameter). In contrast, one particular sine wave modulated model was found to describe the magnetic diffraction pattern well, with a maximum magnetic moment of $4.3 \pm 0.2 \mu_B$, again close to the maximum expected value for Fe^{3+} . In this model, shown in Fig. 3, the spins in a given layer are uniaxial, but the spin axis alternates from layer to layer. Thus, in the first layer the spins lie along $\pm[1, 1, 1/2]$ and in the second layer they lie along $\pm[-1, -1, 1/2]$. The spin amplitude is modulated perpendicular to this direction along $[1, -1, 0]$, i.e., the row direction, as shown in Fig. 3. The fit of the model to the experimental data is illustrated in Fig. 4.

These results may be discussed in terms of the Heisenberg row model. It is easy to show that its $T=0$ ground state is coplanar, and is the same as that of the XY row model.^{6,7} For $J/J' < 2$, this consists of a helical spin structure with a magnetic unit cell consisting of two rows, and an incommensurate repeat distance along the row direction. This magnetic structure minimizes the energy of every elementary triangular plaquette of spins OAB , where spins A and B lie in the same row and spin O lies in the adjacent row [see Fig. 1(b)]. Let θ_O , θ_A , and θ_B denote the orientation, in the XY plane, of the spins on sites O , A , and B , respectively. If θ_O is set equal to 0° , then $\theta_A = 180^\circ - \cos^{-1}(J/2J')$ and $\theta_B = -\theta_A$. The wave vector of this magnetic structure, referred to the primitive unit cell defined in Fig. 1, is $(\theta_A/360^\circ, -\theta_A/360^\circ)$.

The magnetic structures of $\text{CsFe}(\text{SO}_4)_2$ and $\text{RbFe}(\text{SO}_4)_2$ have $\theta_O = 0^\circ$, $\theta_B = 120^\circ$, and $\theta_A = 240^\circ$, corresponding, as expected, to $J/J' = 1$. The magnetic structure adopted by $\text{KFe}(\text{SO}_4)_2$ has wave vector $(0.73, -0.73, 0)$, corresponding to $\theta_A \approx 97^\circ$, $J/J' \approx 0.25$. However, rather than adopting this helical structure, $\text{KFe}(\text{SO}_4)_2$ adopts a sine wave modulated structure with the same wave vector. This structure can be derived from the expected helical structure by suppression of one of its two orthogonal spin components. The adoption of this partially disordered spin structure is consistent with the fact that helical structures cannot develop in a system with lower than tetragonal symmetry at a second order phase transition.¹⁷ In fact, Sólyom¹⁸ showed that for the C -centered orthorhombic structure of MnSO_4 , the helical spin structure can only arise via three second-order transitions. The observation of a sine wave modulated structure well below the ordering temperature in $\text{KFe}(\text{SO}_4)_2$ is nevertheless surprising, as it implies both substantial anisotropy to fix the spin direction, and also large-amplitude spin fluctuations persisting to low temperature. The origin of this spin structure leaves an intriguing problem for future investigation.

ACKNOWLEDGMENT

It is a pleasure to thank Dr. J. P. Attfield for bringing to our attention the work on the C -centered orthorhombic compounds.^{10,11}

Phase transition and phase diagram of the $J_1 - J_2$ Heisenberg model on a simple cubic lattice

C. Pinettes and H. T. Diep

Laboratoire de Physique Théorique et Modélisation, Université de Cergy-Pontoise 2, Avenue Adolphe Chauvin, 95302 Cergy-Pontoise Cedex, France

By extensive standard and histogram Monte Carlo simulations, we show that the magnetic phase transition is of first order in the frustrated $J_1 - J_2$ Heisenberg model on a simple-cubic lattice.

Despite the infinite ground-state degeneracy, the system is shown to retain only the collinear spin configurations at low temperatures. © 1998 American Institute of Physics.

I. INTRODUCTION

Various properties of frustrated spin systems have been extensively investigated during the last 15 years.¹ Nevertheless, several questions remain controversial. In particular, the nature of the phase transition from a noncollinear ground state (GS) to the paramagnetic state is not yet understood at present.

In a frustrated system with vector spins (XY or Heisenberg), the frustration is uniformly distributed on all spins, generally causing a noncollinear GS with very high or infinite degeneracy. Some well-known examples are the antiferromagnetic face-centered cubic (fcc) lattice,^{2,3} the so-called fully frustrated simple-cubic (SC) lattice,⁴ the antiferromagnetic hexagonal-close-packed (hcp) lattice,⁵ the stacked triangular antiferromagnets,⁶ the two-dimensional Villain XY model,⁷ and the XY model on the check-board lattices.⁸ This great degeneracy with a noncollinear ground state gives rise to both a rich behavior on the finite temperature properties such as the nature of ordering and on the phase transition.

The purpose of this work is to study the frustrated SC lattice with antiferromagnetic nearest neighbors (NN) and next-nearest-neighbor (NNN) interactions, J_1 and J_2 , respectively. We are particularly interested in the frustrated region of the phase diagram, when J_2 is strong. Extensive Monte Carlo (MC) simulations, including histogram calculations, have been performed to clarify the nature of the ordering and of the phase transition.

II. MODEL

For this purpose, we consider a classical Heisenberg model with the Hamiltonian

$$H = \sum_{\langle ij \rangle} J_1 \mathbf{S}_i \cdot \mathbf{S}_j + \sum_{\langle\langle ij \rangle\rangle} J_2 \mathbf{S}_i \cdot \mathbf{S}_j, \quad (1)$$

where \mathbf{S}_i is a vector spin of unit length occupying the i th lattice site and the sums $\langle \rangle$ and $\langle\langle \rangle\rangle$ run over NN and NNN pairs, respectively. All interactions are antiferromagnetic (>0). Hereafter, the energy and temperature will be measured in units of J_1 .

For Heisenberg spins, the classical ground state can be determined numerically by an iterative procedure minimizing the local energies until the internal energy is stabilized.⁴

It is given as follows: for $0 < J_2 < 0.25 J_1$, the classical GS is the antiferromagnetic structure. For $0.25 J_1 < J_2$ the classical GS has an infinite degeneracy, apart from the global rotation. It is divided into eight sublattices, the elementary cubes containing two tetrahedra formed by the NNN sites and stacked as in Fig. 1(a). The spin configurations a, b, c, and d of the NNN tetrahedra are those of the elementary tetrahedra in the GS of the fcc antiferromagnets:² each NNN tetrahedron is characterized by two angles, θ , formed by two up spins (or two down spins) and ϕ , formed by the plane containing the two up spins and the plane containing the two down spins (see Ref. 2). The three collinear configurations (one line up, one line down) are particular GS configurations in this range of parameters [see Fig. 1(b)].

We have performed standard MC simulations using the sample sizes of $N = 12^3 - 18^3$ spins with periodic boundary conditions. Starting from a random spin configuration as the initial condition for the MC simulations, we have calculated: the internal energy per spin U , the specific heat per spin C_v , the magnetic susceptibility per spin $\langle \chi \rangle$, and the average sublattice magnetization m_s , as functions of temperature T . At a given T , 10 000 MC steps per spin have been discarded for equilibrating and 10 000 MC steps per spins have been used for averaging. Random initial conditions and such long runs

FIG. 1. (a) The general GS spin configurations for $0.25 J_1 < J_2$. It is decomposed into two NNN tetrahedra, defined by the void and solid circles. The spin orientations of the four sublattices a, b, c, and d are the same as in the antiferromagnetic face-centered cubic lattice: it is given by two angles θ and ϕ (see Ref. 2). (b) The collinear configurations (one line up, one line down) are particular GS configurations for $0.25 J_1 < J_2$. There are two other equivalent configurations with lines along the two other directions of the cubic lattice.

FIG. 2. Phase diagram of the SC J_1 - J_2 lattice in the space $(T, J_2/J_1)$. I, II, and III design antiferromagnetic, collinear [see Fig. 1(a)], and paramagnetic phases, respectively. First-order transitions are shown by black circles for $0.25 J_1 < J_2$. Void circles indicate second-order transitions for $0 < J_2 < 0.25 J_1$. The dashed line indicates the critical value $J_2/J_1 = 0.25$.

were used in order to detect the nature of ordering at finite T as seen below.

III. RESULTS

Figure 2 displays the phase diagram in the phase space $(T, J_2/J_1)$. For $0 < J_2 < 0.25 J_1$, there is a second-order transition from the antiferromagnetic structure to the paramagnetic state at finite temperature. When $0.25 J_1 < J_2$, there is a first-order like transition between the infinitely degenerated GS and the paramagnetic state. At the limit $J_1 = 0$ or $J_1 = \infty$, the SC lattice is decoupled into two independent fcc sublattices. The different physical quantities are shown in Fig. 3 in this range of parameters. They all show a discontinuity at $T_c = 0.33$ for $J_2/J_1 = 0.26$. In order to confirm the nature of the phase transition, we have used the histogram MC simulations.⁹ We discarded 500 000 MC steps per spin for equilibrating and calculated the energy histogram $P(E)$ at the transition temperature over the next one million MC steps. $P(E)$ is shown in Fig. 4 where two peaks are observed at $T_0 = 0.330$ for $J_2/J_1 = 0.26$. This bimodal distribution is a clear evidence of the first-order character of the transition suggested above. Note that long run is necessary to observe the two-peak structure. Less than one million MC steps per spin, the two peaks are not equally developed.

Another interesting point in Fig. 2 is the nature of ordering at low temperature in the frustrated range $0.25 J_1 < J_2$. A natural way to find the nature of ordering at finite temperature is to use the heating procedure from a disordered state and to analyze the spin structure. We used in our runs as order parameters the three staggered magnetizations defined for the collinear configuration shown in Fig. 1(a) and the two other equivalent configurations with lines along the two other directions of the cubic lattice. The results show (see Fig. 5) that just below T_c the system is ordered in one of these three collinear configurations. Thermal (or quantum) fluctuations lift the degeneracy and select collinear configurations. This verifies the conjecture by Henley,¹⁰ in analogy with what was called "order by disorder" in the Ising case,¹¹ as the Heisenberg fcc antiferromagnets,^{2,3} the hcp antiferromagnets,⁵ and the stacked triangular antiferromagnets.⁶

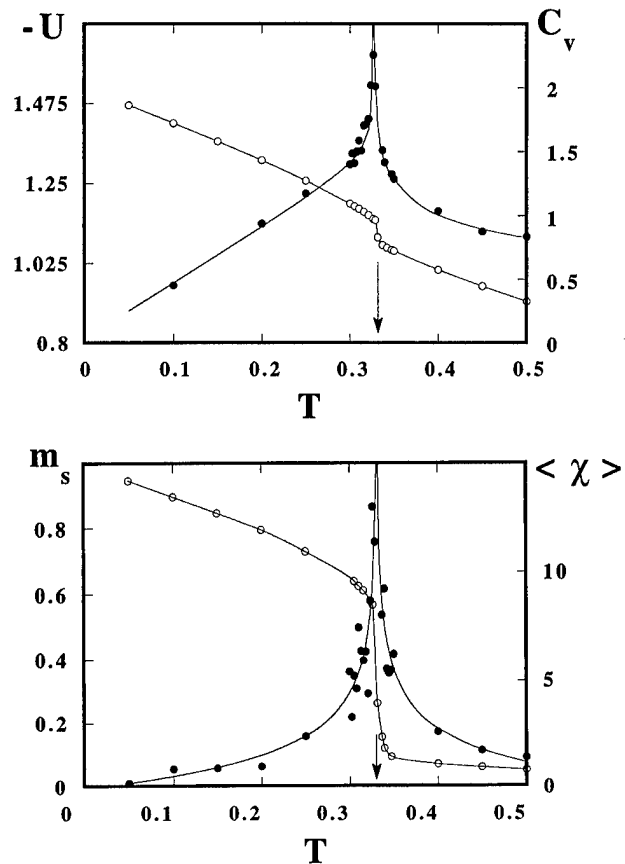

FIG. 3. Thermodynamical quantities as functions of temperature T for $J_2/J_1 = 0.26$. (a) On the left-hand scale, the internal energy per spin U (void circles) and on the right-hand scale, the specific heat per spin C_v (black circles); (b) on the left-hand scale, the average sublattice magnetization m_s (void circles) and on the right-hand scale, the magnetic susceptibility per spin $\langle \chi \rangle$ (black circles). The full curves are a fit to the MC data. The vertical arrows indicate $T_c = 0.33$.

Finally, let us notice that the first-order transition between the collinear phase and the paramagnetic phase can be explained as follows: in the collinear configuration, the infinite degeneracy is reduced to three (apart from the global

FIG. 4. The energy histogram $P(E)$, E being the total energy, for $J_2/J_1 = 0.26$ at a temperature very close to the transition temperature, $T_0 = 0.330$. The energy E is given for the total number of spins $N = 18^3$. The bimodal distribution is a signature of a first-order transition.

FIG. 5. The three staggered magnetizations defined for the collinear configuration shown in Fig. 1(a) are reported as functions of temperature T for $J_2/J_1 = 0.4$. The full curve is a fit to the MC data.

rotation) since there are three ways to choose the antiparallel spin pairs in a tetrahedron. This threefold degeneracy is reminiscent of the three-state Potts model in three dimensions which is known to undergo a first-order transition. This may be the origin of the first-order line observed here, as in the Heisenberg fcc antiferromagnets^{2,3} and the hcp antiferromagnets.⁵

Nevertheless, the nature of the phase transition in non-collinear spin systems (including helimagnets) is not yet clear since some of them exhibit first-order^{2,3,5,8} character and others show a second-order transition unknown universality class.⁶

IV. CONCLUSION

In conclusion, we note that the different thermodynamical quantities determined as functions of temperature suggest

a first-order character of the phase transition in the frustrated J_1-J_2 simple-cubic lattice with vector spins. This first-order character is confirmed by histogram MC simulations. Finally, we have shown that there is an order by disorder effect in these systems: the thermal fluctuations lift the infinite degeneracy and select collinear configurations.

Spin fluctuations and thermal expansion of $\text{La}(\text{Ni}_x\text{Al}_{1-x})_{13}$ amorphous alloys

A. Fujita^{a)} and K. Fukamichi

Department of Materials Science, Graduate School of Engineering, Tohoku University,
Sendai 980-77, Japan

The influences of spin fluctuations on the magnetization M and thermal expansion for $\text{La}(\text{Ni}_x\text{Al}_{1-x})_{13}$ amorphous alloys have been investigated. The spontaneous magnetization obeys a $M^2 - \xi T^{4/3}$ relation and the coefficient ξ is concerned with the dynamical spin fluctuation spectrum. The spontaneous volume magnetostriction in the ferromagnetic state appears due to the thermal variation of the local spin amplitude. The change in the linear thermal expansion coefficient in paramagnetic temperature regions is caused by the saturation of amplitude of the spin fluctuations.

© 1998 American Institute of Physics. [S0021-8979(98)23311-1]

Recently, influences of spin fluctuations on magnetic properties in amorphous weakly itinerant ferromagnetic alloys have been extensively studied.¹⁻⁶ In amorphous alloys, the magnetic properties are changed by the concentration without the limitation of stoichiometry in contrast with that in crystalline compounds.⁵ Therefore, the characteristics of spin fluctuations can be studied more closely in connection with the stability of the ferromagnetic state. Strictly speaking, however, it should be noted that the atomic short-range order varies with the concentration in amorphous alloys⁷ and the recent theoretical studies point out that the stability of ferromagnetism is drastically influenced by the change of the atomic short-range order.^{8,9} The structure of $\text{La}(\text{Ni}_x\text{Al}_{1-x})_{13}$ amorphous alloys can remove the problem mentioned above, namely, the local structure in the present amorphous alloys is well defined by the icosahedral clusters consisting of Ni and Al atoms as observed in NaZn_{13} -type crystalline compounds in a wide concentration range.¹⁰ The present amorphous alloys are useful, therefore, to investigate explicitly spin fluctuation characteristics.

$\text{La}(\text{Ni}_x\text{Al}_{1-x})_{13}$ ($0.90 \leq x \leq 0.95$) amorphous alloys were prepared by high-rate dc sputtering on a water-cooled Cu substrate. The substrate was mechanically removed before the magnetization measurement. The temperature and magnetic field dependences of the magnetization were measured with a SQUID magnetometer.

Temperature dependence of the spontaneous magnetization $M(0, T)$ for $x=0.925$ and 0.95 is plotted in the form of $M(0, T)^2 - T^{4/3}$ in Fig. 1. The value of $M(0, T)$ is deduced from the isothermal magnetization $M(H, T)$ curves. The linear relation is observed in the temperature range above about $T_c/2$ for $x=0.95$ and $0.3 T_c$ for $x=0.925$. According to the theory on exchange enhanced spin fluctuations with mode-mode coupling, the $M^2 - T^{4/3}$ relation is explained as a result of a strong renormalization effect of paramagnon-like modes of spin fluctuations to the magnetic free energy.¹¹⁻¹³ The coefficient ξ in the $M^2 - \xi T^{4/3}$ relation is associated with the dynamical properties of spin fluctuations and expressed by the following expression^{14,15}:

$$\xi = K \frac{1}{T_A T_0^{1/3}}, \quad (1)$$

where K is the constant and the parameters T_A and T_0 characterize the dispersion of the static q -dependent susceptibility and the dynamical spin fluctuation spectrum. The following relation between these parameters and magnetization curve is derived by assuming that the sum of amplitudes of thermal and zero-point spin fluctuations is conserved at finite temperatures.¹⁶

$$-2c \left(\frac{T_c}{T_0} \right)^{4/3} k_B T_A p_s + \frac{4k_B T_A^2}{15T_0} \frac{p_s^3}{8} = 2\mu_B H, \quad (2)$$

where k_B and μ_B are the Boltzmann constant and the Bohr magneton, respectively, p_s equals $2M(0, 0)$, and c is 0.335. The parameters T_A and T_0 for the present amorphous alloys have been evaluated from the Arrott plots in our previous paper² by using Eq. (2). In Fig. 2, the coefficients ξ for $x=0.90, 0.925$, and 0.95 are plotted against $1/(T_A T_0^{1/3})$, and the proportional relation is confirmed. Therefore, the relation (1) is well established in the present amorphous alloys. It should be emphasized that the relations (1) and (2) are valid even in amorphous alloys, although these were originally applied to crystalline systems.¹³

FIG. 1. Temperature dependence of the spontaneous magnetization plotted in the form of $M(0, T)^2 - T^{4/3}$ for $\text{La}(\text{Ni}_x\text{Al}_{1-x})_{13}$ ($x=0.95$ and 0.925) amorphous alloys.

FIG. 2. The coefficient ξ plotted against $1/(T_A T_0^{1/3})$ for $\text{La}(\text{Ni}_x\text{Al}_{1-x})_{13}$ amorphous alloys. The parameters ξ , T_A , and T_0 are explained in the text.

Thermal variation of the amplitude of spin fluctuations is reflected on the thermal expansion.¹⁷ Figure 3 shows the temperature dependence of the spontaneous volume magnetostriction $\omega_m(T)$ for $x=0.925$ and 0.95 . The value of $\omega_m(T)$ is obtained from the comparison between the observed and hypothetical nonmagnetic thermal expansion curves, as shown in the inset in Fig. 3. The hypothetical nonmagnetic thermal expansion curve, represented by a dashed line, is obtained from the Grüneisen relation with referring the Debye model and the free-electron model for phonon and electron contribution, respectively. The Debye temperature θ_D is assumed to be the same value of $\theta_D = 280$ K for $\text{La}(\text{Fe}_x\text{Al}_{1-x})_{13}$ amorphous alloys obtained from the Brillouin scattering.¹⁸ The magnitude of $\omega_m(T)$ continuously decreases with increasing temperature and smears around the Curie temperature. Such behavior is an indication that the amplitude of local spin density varies with temperature and continuously decreases up to the Curie temperature.^{13,17} Detailed influence of spin fluctuations on $\omega_m(T)$ will be discussed elsewhere.¹⁰

Theories on spin fluctuations in itinerant ferromagnets predict that the amplitude of spin fluctuations increases with the temperature and the thermal variation of spin fluctuations gives a positive contribution to the thermal expansion coefficient in paramagnetic temperature ranges.^{13,17} Figure 4

FIG. 3. Temperature dependence of the spontaneous volume magnetostriction $\omega_m(T)$ for $\text{La}(\text{Ni}_x\text{Al}_{1-x})_{13}$ ($x=0.95$ and 0.925) amorphous alloys. The inset shows the thermal expansion curve of $x=0.95$, together with a hypothetical dashed curve in a nonmagnetic state. The Curie temperature is indicated by the arrows.

FIG. 4. Temperature dependence of the linear thermal expansion coefficient for $\text{La}(\text{Ni}_x\text{Al}_{1-x})_{13}$ amorphous alloys in the paramagnetic temperature region. The inset shows the temperature dependence of the inverse magnetic susceptibility for $x=0.90$ and 0.925 . The characteristic temperature T^* is given by the arrows.

shows the linear thermal expansion coefficient (TEC) in paramagnetic temperatures for $x=0.95$, 0.925 , and 0.90 . For itinerant weakly ferromagnets, the contribution of spin fluctuations to TEC, α_m , is represented as

$$\alpha_m = \kappa C_m \frac{dS_L^2(T)}{dT}, \quad (3)$$

where $S_L^2(T)$ is the mean square of the amplitude of local spin fluctuations, C_m and κ are the magnetovolume coupling coefficient and the compressibility, respectively.¹⁷ Generally speaking, S_L^2 increases linearly and hence α_m is almost constant in weakly itinerant ferromagnets.^{11,13,19} The electron contribution is proportional to the temperature.¹⁹ In the temperature region higher than the Debye temperature, the phonon contribution to TEC behaves as the Dulong–Petit law. As mentioned in the preceding section, the Debye temperature of the present amorphous alloys is assumed to be 280 K.¹⁸ Therefore, TEC around room temperature should increase monotonically with the temperature. However, as seen in Fig. 4, a change in the increase occurs in all the curves, shifted to lower temperatures with decreasing x . Because of an apparent concentration dependence, the origin of this anomaly neither is phonons nor electrons but spin fluctuations. Thus, the anomalous temperature dependence of S_L^2 occurs in paramagnetic temperature ranges.

The information on the paramagnetic spin fluctuations in itinerant weakly ferromagnets can be obtained from temperature dependence of paramagnetic susceptibility.¹¹ The inverse magnetic susceptibility $1/\chi$ is proportional to S_L^2 , and a linear thermal variation of S_L^2 gives a Curie–Weiss-like behavior even in itinerant ferromagnets.^{11,13} The inset in Fig. 4 shows the temperature dependence of the inverse magnetic susceptibility for $x=0.90$ and 0.925 . For the present amorphous alloys, $1/\chi$ becomes convex upwards just above T_c and subsequently shows an upturn.² The curving of $1/\chi$ con-

vex upwards is interpreted as a significant increase of S_L^2 .^{13,20} A sudden increase in the slope of $1/\chi$ suggests that the magnitude of S_L^2 arrives at its upper limit because of charge neutrality.^{20,21} After the amplitude of spin fluctuations is saturated at the upper limit value, the spin fluctuations give no contribution to $1/\chi$, resulting in a large slope of $1/\chi$ due to the directional fluctuations of magnetic moments. The starting temperature of the saturation phenomenon, T^* , is obtained from the intersection of the straight lines before and after the change in the slope as indicated by the arrows in Fig. 4. Apparently, TEC changes its magnitude at around T^* , revealing that the saturation of the amplitude of spin fluctuations is its origin.

In summary, the influences of spin fluctuations on the magnetization and thermal expansion are observed in $\text{La}(\text{Ni}_x\text{Al}_{1-x})_{13}$ amorphous alloys. In the ferromagnetic state, the $M^2 - \xi T^{4/3}$ relation appears and the coefficient ξ is closely correlated with the spin fluctuation spectrum. The spontaneous volume magnetostriction is caused by the thermal variation of the local spin amplitude. The linear thermal expansion coefficient in paramagnetic temperature regions changes its magnitude due to the saturation of the amplitude of spin fluctuations.

Magnetic relaxation in $\text{Ga}_{0.6}\text{Mo}_2\text{S}_4$ spinel

T. Taniyama^{a)} and I. Nakatani

National Research Institute for Metals, Tsukuba 305-0047, Japan

Magnetization measurements on $\text{Ga}_{0.6}\text{Mo}_2\text{S}_4$ cluster compound of modified spinel were performed at temperatures from 2 to 30 K. Temperature irreversibility of the magnetization develops just below the ferromagnetic transition temperature. Relaxation isotherms of the thermoremanent magnetizations can be described by a superposition of a stretched exponential and a constant term, and shows distinctive aging effects. This implies the presence of the orientational spin freezing in the ferromagnetic regime of the $\text{Ga}_{0.6}\text{Mo}_2\text{S}_4$. © 1998 American Institute of Physics.

[S0021-8979(98)50611-1]

The molybdenum cluster compound $\text{Ga}_x\text{Mo}_2\text{S}_4$ ($x = 0.5-0.67$) demonstrates fruitful magnetic properties owing to the tetrahedral molybdenum clustering induced by the order of Ga atoms and vacancies on the tetrahedral sites in spinel structure.¹⁻³ In this kind of compound, imperfections of the Ga-vacancy ordering yields significant modification of electronic properties. Recently, Sahoo *et al.* reported the signature of variable-range hopping between the localized states of clusters induced by such imperfections.^{4,5} However, comparatively little attention has been paid to the magnetic properties intrinsically affected by the random atomic arrangement.

The intrigue magnetic properties due to such random effects can be sensitively probed by the thermoremanent magnetization (TRM). In particular, time evolution of the TRM gives distinguishable dynamic response caused by the different physical mechanism. Thus, we employ the time dependent TRM measurements on the $\text{Ga}_{0.6}\text{Mo}_2\text{S}_4$ to elucidate the magnetic nature in the view of the randomness. In this article, we present temperature irreversibility of the magnetization and waiting time dependence of the magnetic relaxation in the ferromagnetic regime.

The method of sample preparation has been described in our previous article.⁶ The x-ray diffraction pattern was indexed on the basis of the lower symmetric spinel structure (space group $F\bar{4}3m$) having $a = 9.737 \text{ \AA}$ and revealed a homogeneity of the prepared sample. With decreasing temperature, splitting of the $h00$ diffraction peaks was observed below the temperature of 43 K, reflecting the structural transition from a space group $F\bar{4}3m$ to $R\bar{3}m$. This is consistent with the results previously reported by Shamrai *et al.*^{2,3} The pellet used for the x-ray diffraction measurement was cut into a size of $1 \text{ mm} \times 1 \text{ mm} \times 5 \text{ mm}$ for the magnetic measurements. Magnetic data were collected using a magnetometer (PPMS, Quantum Design) at temperatures from 2 to 30 K. Temperature dependent magnetizations were measured with increasing temperature under both zero field cooled (ZFC) and field cooled conditions. The time dependent TRM was recorded over four decades of observation time after switching off the cooling magnetic field.

Figure 1 shows the temperature dependent magnetization

and the ac susceptibility at temperatures from 2 to 30 K. The ZFC magnetization exhibits a shallow maximum structure and the maximum temperature shifts towards lower temperatures as the magnetic field increases. The temperature irreversibility of the magnetization also develops just below the ferromagnetic transition temperature T_c , which has been defined to be 17.4 K by the previous nonlinear susceptibility measurements.⁶ The significant irreversibility and the peak structure of the temperature dependent magnetization are typical of the disordered materials, e.g., spin glasses and random ferromagnets. We note that the magnetic feature of the $\text{Ga}_{0.6}\text{Mo}_2\text{S}_4$ is quite similar to that of the reentrant ferromagnetic semiconductor of the indium-doped chalcogenide spinel $\text{CdCr}_2\text{Se}_4:\text{In}$.⁷

Relaxation isotherms were collected after a sequence of waiting for a time of $t_w = 60 \text{ s}$ at the measurement temperature and switching off the cooling fields of 50 Oe and 1 kOe, from which the temperature dependent relaxation rates (Fig. 2) are extracted simply using the logarithmic relaxation decay form:

$$M = M_0 - S \log t, \quad (1)$$

FIG. 1. Temperature dependent zero field cooled and field cooled magnetization in a field of 50 Oe. Temperature dependent ac susceptibility in a modulation field of 2 Oe is also depicted.

^{a)}Electronic mail: taniyama@hagi982.nrim.go.jp

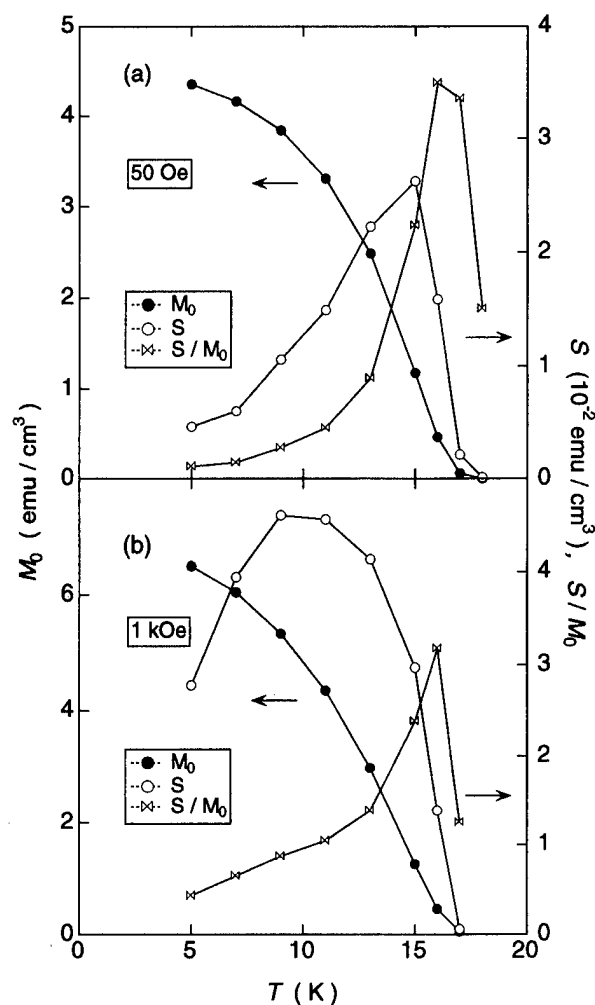

FIG. 2. Temperature dependent relaxation rate S and initial magnetization M_0 in a cooling field of (a) 50 Oe and (b) 1 kOe.

where the S is the relaxation rate and M_0 is the initial magnetization. Although the maximum in the temperature dependent relaxation rate shifts towards lower temperatures with increasing magnetic fields, the normalized relaxation rate S/M_0 hardly shows the field dependence.

Figure 3 illustrates the relaxation dynamics for two extreme waiting times $t_w = 60$ s and $t_w = 10\,800$ s, at 15 K on a logarithmic time scale. In contrast to the concave up profile for $t_w = 60$ s, the relaxation isotherm concaves down after waiting for $t_w = 10\,800$ s in a magnetic field. Such behavior has been frequently observed in the reentrant ferromagnet and the relaxation isotherms can be represented by a superposition of a stretched exponential and a constant term.^{8,9}

$$M = M_0 + M_1 \exp[-(t/\tau)^{1-n}]. \quad (2)$$

The additional constant term has been interpreted on the basis of the reliable picture introduced by Gabay and Thoulouse,¹⁰ in which the longitudinal spontaneous magnetization coexists with the frozen transverse spin component. Within this framework, we fit the experimental data using Eq. (2) over the entire observation time scale (Fig. 3). The best fit parameters are listed in Table I. The values of the fitted parameters τ and n closely correspond to those of FeNiMn reentrant ferromagnet.¹¹

FIG. 3. Time dependent thermoremanent magnetization recorded at 15 K after a sequence of waiting for a time t_w and switching off the cooling magnetic field of 50 Oe. The solid lines are fitted curves in terms of a superposition of a stretched exponential and a constant term.

Mitchler *et al.* carefully investigated the analytical functional forms of the relaxation isotherm in the random ferromagnet PdFe and the reentrant ferromagnet CrFe, and found that the relaxation responses are divided into two groups: a power law and a stretched exponential decay. The former functional form accurately represents the relaxation of the random ferromagnets such as PdFe, while the latter case characterizes the orientational collapse into random spin configurations in the reentrant ferromagnet. Further, the reentrant phase exhibits the system age dependent relaxation although the random ferromagnet shows no measurable aging effects on the relaxation dynamics reflecting the equilibrium aging limit. In the present case, the relaxation isotherms are represented by a stretched exponential superposed on a constant term and show the discernible aging effects. This persuasively indicates that the glassy freezing occurs in the ferromagnetic phase of the $\text{Ga}_{0.6}\text{Mo}_2\text{S}_4$, although the presence of the aging effects on the relaxation isotherms does not offer a definitive criterion for distinguishing the microscopic spin configurations in the disordered materials.

It is not clear whether or not the orientational collapse simultaneously evolves as the ferromagnetic ordering is established. In our previous article, the ferromagnetic transition temperature was determined to be 17.4 K based on the nonlinear susceptibility measurements.⁶ The obtained transition temperature exactly coincides with the temperature below which the dc susceptibility M/H exhibits the field dependence as shown in Fig. 1. On the contrary, the irreversibility in a field of 50 Oe develops below a slightly lower tempera-

TABLE I. Best-fit parameters to a stretched exponential in Eq. (2).

t_w (s)	M_0 (emu/cm³)	M_1 (emu/cm³)	τ (s)	n
60	0.99	0.12	135	0.76
10 800	0.91	0.22	39 000	0.87

ture of 16.5 K. If we assign the glassy freezing with the onset of the irreversibility, the freezing process may sequentially occur after the ferromagnetic transition. Although one may suspect that the irreversibility temperature possibly approaches the T_c with reducing the applied field, we emphasize the coincidence between the irreversibility temperature and the peak temperature of the ac susceptibility in zero bias field. Thus, our picture of the sequential collapse into the randomly orientational spin configurations is plausible.

Finally, we make a brief comments on the origin of the spin-glass-like dynamics. As we have stated before, the magnetic disorder would be mainly driven by the random molybdenum clustering due to the imperfection of the Ga-vacancy ordering. However, we have to claim the instability of the cubic lattice structure at 43 K. Shamrai *et al.* proposed the displacement of the molybdenum atoms to form a Mo_3 complex with a shorter distance in the low-temperature $R3m$ phase and suggested the resultant mixed type of interactions, i.e., indirect exchange interaction and superexchange interaction between molybdenum ions. Thus, the distortion of the crystal lattice should be partly responsible for the frustrating interactions which promote the glassy behaviors in the $\text{Ga}_{0.6}\text{Mo}_2\text{S}_4$.

We summarize the magnetic feature of the $\text{Ga}_{0.6}\text{Mo}_2\text{S}_4$

deduced from the magnetic measurements. The random orientational freezing is inferred from the temperature irreversibility and the relaxation dynamics described by a superposition of a stretched exponential and a constant term, which is further reinforced by the specific aging effects in the ferromagnetic regime. In order to get the convincing evidence for the spin configurations, further microscopic measurements such as neutron scattering or nuclear magnetic resonance measurements are required.

New bulk amorphous Fe-(Co,Ni)-M-B (M=Zr,Hf,Nb,Ta,Mo,W) alloys with good soft magnetic properties

Akihisa Inoue, Tao Zhang, and Hisato Koshida

Institute for Materials Research, Tohoku University, Katahira 2-1-1, Aoba-ku, Sendai 980-77, Japan

Akihiro Makino

Central Research Laboratory, Alps Electric Co. Ltd., Higashi-Takami 1-3-5, Nagaoka 940, Japan

We have found that an amorphous phase with a wide supercooled liquid region reaching 85 K before crystallization is formed in Fe-(Co, Ni)-(Zr, Nb, Ta)-B, Fe-Co-(Zr, Nb)-(Mo, W)-B and Co-Fe-Zr-B systems. The high stability of the supercooled liquid enabled the production of bulk amorphous alloys with diameters up to 5 mm by copper mold casting. These amorphous Fe-(Co, Ni)-M-B alloys exhibit good soft magnetic properties, i.e., saturation magnetization of 0.95 to 1.1 T, low coercivity of 1 to 8 A/m, Curie temperature of 560 to 590 K and low magnetostriction of $8-14 \times 10^{-6}$. The effective permeability of the Co-based alloys exceeds 25 000 at 1 kHz and keeps high values above 5000 at the high frequency of 1 MHz. The permeability at 1 MHz is much higher than those for any kinds of soft magnetic materials. The frequency at which the imaginary part of permeability shows a maximum is also about 1 MHz. The success of synthesis of new Fe- and Co-based amorphous alloys with good soft magnetic properties and high glass-forming ability is promising for future development of a new type of soft magnetic material. © 1998 American Institute of Physics. [S0021-8979(98)47111-1]

It is well known that Fe- and Co-based amorphous alloys exhibit good soft magnetic properties. The soft magnetic properties have been characterized as the achievement of high saturation magnetization for Fe-based alloys and high permeability (μ_e) and zero magnetostriction for Co-based alloys.¹ However, these soft magnetic amorphous alloys have usually been prepared in a thin sheet form with a thickness below 50 μm and in a wire form with a diameter below 120 μm .² The small maximum thickness resulting from the low glass-forming ability has prevented the further extension of application fields as magnetic materials. Consequently, great effort has been devoted to search new ferromagnetic amorphous alloys with higher glass-forming ability for the last two decades. Recently, Inoue *et al.* have succeeded in finding a number of amorphous alloys with high glass-forming ability in Ln-Al-TM,³ Mg-Ln-TM,⁴ Zr-Al-TM⁵ and Pd-Cu-Ni-P⁶ (Ln=lanthanide metal, TM=transition metal) systems and in preparing bulk amorphous alloys with maximum diameters up to about 72 mm by copper mold casting.⁶ Although these bulk amorphous alloys have been limited to the nonferrous alloys without ferromagnetism, the findings of the above-described bulk amorphous alloys have enabled the derivation of the three empirical rules for achievement of large glass-forming ability.⁷⁻¹⁰ That is, (1) multicomponent alloys systems consisting of more than three elements, (2) significant difference in atomic size ratios above 12% among the main constituent elements, and (3) negative heats of mixing among their elements. Based on the three empirical rules, we have subsequently searched ferromagnetic Fe- and Co-based amorphous alloys with large glass-forming ability

leading to the production of bulk amorphous alloys. As a result, we have found that multicomponent Fe-(Co, Ni)-(Zr, Nb, Ta)-B, Fe-Co-(Zr, Nb)-(Mo, W)-B and Co-Fe-(Zr, Nb)-B amorphous alloys exhibit a wide supercooled liquid region reaching 80 K before crystallization¹¹⁻¹³ and can be produced in a cylindrical form with diameters up to about 5 mm by copper mold casting.¹⁴ This is believed to be the first evidence on the preparation of ferromagnetic Fe- and Co-based bulk amorphous alloys. This paper aims to present the composition range in which amorphous alloys in Fe-(Co, Ni)-M-B (M=Zr, Hf, Nb, Mo, W) systems, are formed either by copper mold casting or by melt spinning and to examine the compositional dependence of the thermal stability and magnetic properties of the Fe- and Co-based amorphous alloys.

Multicomponent alloys with composition $\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_{10}\text{B}_{20}$, $\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_8\text{Nb}_2\text{B}_{20}$, $\text{Fe}_{60}\text{Co}_8\text{Zr}_{10}\text{Mo}_5\text{W}_2\text{B}_{15}$, and $\text{Co}_{56}\text{Fe}_{16}\text{Zr}_8\text{B}_{20}$ were prepared by arc melting a mixture of pure metals and pure B crystal in an argon atmosphere. These compositions were chosen because of the appearance of a supercooled liquid region of 35 to 85 K. From these prealloyed ingots, cylindrical samples with a constant length of about 50 mm and different diameters in the range of 0.5 to 6 mm were prepared by injection casting of the molten alloy into copper molds with cylindrical cavities. For comparison, amorphous ribbons with a cross section of $1 \times 0.02 \text{ mm}^2$ were produced by melt spinning. The amorphicity was examined by x-ray diffractometry and optical microscopy (OM). The OM sample was etched for 10 s at 293 K in a solution of 0.5% hydrofluoric acid and 99.5%

FIG. 1. Outer morphology and surface appearance of cast $\text{Fe}_{60}\text{Co}_8\text{Zr}_{10}\text{Mo}_5\text{W}_2\text{B}_{15}$ alloy cylinders with diameters 3 and 5 mm.

distilled water. The specific heat associated with glass transition, supercooled liquid region and crystallization was measured at a heating rate of 0.67 K/s with a differential scanning calorimeter (DSC). Saturation magnetization (I_s) and coercivity (H_c) under a field of 800 kA/m were measured at room temperature with a vibrating sample magnetometer (VSM). Hysteresis B-H loop under a magnetic field of 1.6 kA/m was also measured for the melt-spun ribbons with a B-H loop tracer. Permeability (μ_e) was evaluated in a frequency range of 1 to 10^4 kHz with an impedance analyzer. Saturated magnetostriction (λ_s) was measured under a field of 240 kA/m by a three-terminal capacitance method. Curie temperature (T_c) was determined by extrapolating the I - T curve in the constant coupling approximation manner. Electrical resistivity measurement was made by the four-probe method at room temperature.

FIG. 2. DSC curves of the cast amorphous $\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_8\text{Nb}_2\text{B}_{20}$, $\text{Fe}_{60}\text{Co}_8\text{Zr}_{10}\text{Mo}_5\text{W}_2\text{B}_{15}$, and $\text{Co}_{56}\text{Fe}_{16}\text{Zr}_8\text{B}_{20}$ alloys.

TABLE I. Maximum sample thickness (t_{max}) and thermal stability (T_g , ΔT_x , and T_g/T_m) of the $\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_{10}\text{B}_{20}$, $\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_8\text{Nb}_2\text{B}_{20}$, $\text{Fe}_{60}\text{Co}_8\text{Zr}_{10}\text{Mo}_5\text{W}_2\text{B}_{15}$, and $\text{Co}_{56}\text{Fe}_{16}\text{Zr}_8\text{B}_{20}$ amorphous alloys.

Alloy	Maximum sample thickness	Thermal stability		
	t_{max} (mm)	T_g (K)	ΔT_x (K)	T_g/T_m
$\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_{10}\text{B}_{20}$	2	814	73	0.60
$\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_8\text{Nb}_2\text{B}_{20}$	2	828	85	-
$\text{Fe}_{60}\text{Co}_8\text{Zr}_{10}\text{Mo}_5\text{W}_2\text{B}_{15}$	6	898	64	0.63
$\text{Co}_{56}\text{Fe}_{16}\text{Zr}_8\text{B}_{20}$	-	839	39	-

Figure 1 shows the outer morphology of the bulk $\text{Fe}_{60}\text{Co}_8\text{Zr}_{10}\text{Mo}_5\text{W}_2\text{B}_{15}$ cylinders with diameters of 3 and 5 mm. These samples have smooth surface and metallic luster. No contrast of a crystalline phase is seen over the outer surface. The x-ray diffraction patterns showed a main halo peak with a wave vector $K_p (=4\pi \sin \theta/\lambda)$ around 29.6 nm^{-1} and no crystalline peak is observed even for the 5 mm ϕ sample. The optical micrographs of the cross section of the two samples also revealed a featureless contrast in an etched state using a hydrogen fluoride acid. These results indicate that the bulk cylinders are composed of an amorphous phase in the diameter range up to 5 mm. It is to be noticed that the maximum thickness (t_{max}) is about 3 times larger than the largest value (2 mm for $\text{Fe}_{72}\text{Al}_5\text{Ga}_2\text{P}_{10}\text{C}_6\text{B}_4\text{Si}_1$) for Fe-based amorphous alloys reported up to date. Figure 2 shows the DSC curves of the bulk amorphous $\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_8\text{Nb}_2\text{B}_{20}$ and $\text{Fe}_{60}\text{Co}_8\text{Zr}_{10}\text{Mo}_5\text{W}_2\text{B}_{15}$ cylinders of 1 to 3 mm in diameter and $\text{Co}_{56}\text{Fe}_{16}\text{Zr}_8\text{B}_{20}$ of 1 mm in width. These amorphous alloys exhibit the sequential transition of glass transition, supercooled liquid and crystallization. The supercooled liquid region, ΔT_x , defined by the difference between the glass transition temperature (T_g) and the onset temperature of crystallization (T_x) is as large as 39 to 85 K and the crystallization from the supercooled liquid occurs through a distinct

FIG. 3. Frequency dependence of real (μ') and imaginary (μ'') parts of permeability for amorphous $\text{Co}_{56}\text{Fe}_{16}\text{Zr}_8\text{B}_{20}$ alloys of 1 mm in width subjected to annealing for 600 s at 750 and 800 K.

TABLE II. Magnetic properties (I_s , H_c , μ_e at 1 kHz and λ_s) of $\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_{10}\text{B}_{20}$, $\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_8\text{Nb}_2\text{B}_{20}$, and $\text{Co}_{56}\text{Fe}_{16}\text{Zr}_8\text{B}_{20}$ amorphous alloys.

Alloy	Soft magnetic properties					
	I_s (T)	H_c (A/m)	μ_e (1 kHz)	μ_e (1 MHz)	λ_s (10^{-6})	T_c (K)
$\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_{10}\text{B}_{20}$	0.96	2.0	19 100	-	10	594
$\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_8\text{Nb}_2\text{B}_{20}$	0.75	1.1	25 000	-	13	531
$\text{Co}_{56}\text{Fe}_{16}\text{Zr}_8\text{B}_{20}$	0.77	8.3	17 100	5500	14	-

exothermic reaction. The crystallites were identified to consist of α -Fe, Fe_2Zr , Fe_8B , MoB , and W_2B phases for the $\text{Fe}_{60}\text{Co}_8\text{Zr}_{10}\text{Mo}_5\text{W}_2\text{B}_{15}$ sample heated to the temperature just above the exothermic peak. Thus, the crystallization is due to the simultaneous precipitation of the five crystalline phases. This crystallization mode is in agreement with that⁸ for other bulk amorphous alloys. The largest ΔT_x is 85 K for $\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_8\text{Nb}_2\text{B}_{20}$, being larger than the largest values (57 to 67 K) for Fe-(Al, Ga)-(P, C, B, Si)^{14,15} and nonferrous Pd- and Pt-based amorphous alloys.^{16,17}

Table I summarizes the t_{\max} , T_g , ΔT_x and T_g/T_m of the Fe-(Co, Ni)-M-B amorphous alloys. We also evaluated the reduced glass transition temperature (T_g/T_m). The T_m was 1420 K for $\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_{10}\text{B}_{20}$ and 1416 K for $\text{Fe}_{60}\text{Co}_8\text{Zr}_{10}\text{Mo}_5\text{W}_2\text{B}_{15}$ and the T_g/T_m was evaluated to be 0.60 for the former alloy and 0.63 for the latter alloy. Considering that T_g/T_m is 0.54 for $\text{Fe}_{80}\text{P}_{12}\text{B}_4\text{Si}_4$ ¹⁸ and 0.57 for $\text{Fe}_{73}\text{Al}_5\text{Ga}_2\text{P}_{11}\text{C}_4\text{B}_4\text{Si}_1$,¹⁸ the present T_g/T_m values are believed to be the highest among all Fe-based amorphous alloys.

Figure 3 shows the real and imaginary parts of permeability (μ' and μ''), respectively, as a function of frequency (f) for the $\text{Co}_{56}\text{Fe}_{16}\text{Zr}_8\text{B}_{20}$ amorphous ribbon of 1 mm width. The μ' of the $\text{Co}_{56}\text{Fe}_{16}\text{Zr}_8\text{B}_{20}$ ribbon keeps high values of 17 100 to 5500 in the high frequency range up to 1 MHz and decreases with a further increase in frequency to 10 MHz. It is to be noticed that the frequency at which the maximum μ'' is obtained for the ribbon is as high as about 1 MHz. The $\mu''(f)$ data indicate that the Co-Fe-Zr-B alloy can keep high μ' values up to 1 MHz of the maximum μ'' point. The μ' value is much higher than those for the Fe-Si-B amorphous ribbon with the same width of 1 mm over the whole frequency range. Furthermore, the μ' values of the $\text{Co}_{56}\text{Fe}_{16}\text{Zr}_8\text{B}_{20}$ alloy is higher than those for the Co-Fe-Ni-Mo-Si-B amorphous alloy with zero λ_s in the high frequency range above 10 kHz. The electrical resistivity (ρ_{RT}) of the $\text{Co}_{56}\text{Fe}_{16}\text{Zr}_8\text{B}_{20}$ alloy is $1.70 \mu\Omega \text{ m}$, which is higher as compared with $1.34 \mu\Omega \text{ m}$ for $\text{Co}_{70.3}\text{Fe}_{4.7}\text{B}_{10}\text{Si}_{15}$, $1.37 \mu\Omega \text{ m}$ for $\text{Fe}_{78}\text{B}_{13}\text{Si}_9$ (METGLAS 2605S-2) and $1.42 \mu\Omega \text{ m}$ for the Co-Fe-Ni-Si-B METGLAS 2714A alloy.¹⁹ Consequently, the excellent high-frequency permeability for the present alloys is probably due to the decrease in eddy current loss resulting from the higher ρ_{RT} . It is concluded that the present Co-based amorphous alloys have good soft magnetic properties and high stability of supercooled liquid against crystallization.

Table II summarizes the t_{\max} , I_s , H_c , μ_e at 1 kHz and λ_s for the new amorphous Fe-(Co, Ni)-M-B alloys. These amorphous alloys exhibit good soft magnetic properties in an

annealed (800 K, 300 s) state, i.e., high I_s of 0.74 to 0.96 T, low H_c of 1.1 to 3.2 A/m, high μ_e of 12 000 to 25 000 and low λ_s of 10×10^{-6} to 14×10^{-6} . The H_c and μ_e are superior to those for conventional Fe-Si-B amorphous ribbons,²⁵ presumably because of the lower λ_s .

Finally, the reason for the large ΔT_x and t_{\max} for the Fe-based amorphous alloys is discussed in the framework of the three empirical rules for the achievement of high glass-forming ability. The base composition is the Fe-Zr-B system which satisfies the three empirical rules. The addition of Nb, Ta, Mo, and W is effective for the increase in the degree of the satisfaction of the empirical rules. That is, the addition of these elements causes the more sequential change in the atomic size in the order of $\text{Zr} \gg \text{Nb} > \text{W} > \text{Mo} > \text{Fe} > \text{Co} > \text{B}$ as well as the generation of new atomic pairs with various negative heats of mixing. In the supercooled liquid in which the three empirical rules are satisfied at a high level, the topological and chemical short-range orderings are enhanced, leading to the formation of a highly dense random packed structure with low atomic diffusivity. The largest ΔT_x is 85 K for $\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Zr}_8\text{Nb}_2\text{B}_{20}$ and 35 K for $\text{Co}_{56}\text{Fe}_{16}\text{Zr}_8\text{B}_{20}$ and the t_{\max} reaches 5 mm for $\text{Fe}_{60}\text{Co}_8\text{Zr}_{10}\text{Mo}_5\text{W}_2\text{B}_{15}$. Furthermore, these bulk amorphous alloys exhibit good soft magnetic properties. These novel characteristics allow us to expect that the new Fe- and Co-based bulk amorphous alloys are used as engineering materials.

Influence of Si addition on thermal stability and soft magnetic properties for Fe–Al–Ga–P–C–B glassy alloys

T. Mizushima and A. Makino

Central Research Laboratory, Alps Electric Co., Ltd., 1-3-5 Higashitakami, Nagaoka 940, Japan

A. Inoue

Institute for Materials Research, Tohoku University, 2-1-1 Katahira, Aoba-ku, Sendai 980-77, Japan

The thermal stability of the supercooled liquid region (ΔT_x), defined by the difference between crystallization temperature (T_x) and glass transition temperature (T_g), and soft magnetic properties were investigated for $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ ($x=0-4$) and $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$ ($x=0-3$) glassy alloys. The thermal stability, glass forming ability and effective permeability (μ_e) at 1 kHz are improved with the replacement of P by 1–3 at. % Si for $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ and by 1–2.6 at. % Si for $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$. The ΔT_x and the maximum thickness for glass formation (t_{\max}) reach maximum values of 60 K and 280 μm , respectively, for $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ and 34 K and 220 μm , respectively, for $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$ at $\text{Si(at. \%)} / (\text{Si(at. \%)} + \text{P(at. \%)}) = 0.24$. Core losses for $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{8.4}\text{C}_5\text{B}_4\text{Si}_{2.6}$ glassy alloy is much lower than that for amorphous Fe–Si–B alloy at the sheet thickness more than 70 μm . Therefore, it can be said that the Fe–Al–Ga–P–C–B–Si glassy alloys are useful for inductive applications because of their bulky shape and good soft magnetic properties. © 1998 American Institute of Physics. [S0021-8979(98)47211-6]

Since the discovery of good soft magnetic properties for Fe-based amorphous alloys,^{1,2} the development of thicker ferromagnetic amorphous alloy sheets has been desired for further extension of application fields for these alloys. The thicker sheets have been also desired because the reduction of lamination process for transformers and/or inductors is expected by using thicker sheets. Furthermore, lamination factor will be improved with use of thicker sheets. However, to date, it has been known that the preparation of amorphous sheets with thicknesses over 100 μm was very difficult because of the necessity of high cooling rates resulting from their low glass-forming ability.³ Recently, bulk glassy alloys have been formed in multicomponent Mg-,^{4,5} Ln-,^{6,7} Zr-,⁸⁻¹¹ and Pd-¹² based (Ln=lanthanide metal) alloy systems. These bulk glassy alloys have a wide supercooled liquid region above 60 K before crystallization. There is a clear tendency for the glass-forming ability to increase with increasing ΔT_x . The above mentioned glassy alloys always satisfy the following three empirical rules¹³⁻¹⁵ for achievement of a large glass-forming ability; i.e., (1) multicomponent alloy systems consisting of more than three elements, (2) significantly differential atomic size ratios above about 12% among the main constituent elements, and (3) negative heats of mixing among their elements. Based on the three empirical rules, we have searched for new Fe-based glassy alloys with a wide supercooled liquid region before crystallization. As a result, we have already reported that the Fe-based glassy alloy sheets with thicknesses up to 190 μm were prepared by using a melt spinning technique in Fe–(Al, Ga)–(P, C, B, Si) where the three group elements satisfied the three empirical rules.¹⁶ We have tried to further investigate the composition to prepare a much thicker sample. This paper investigates the influence of Si addition on the thermal stability of the supercooled liquid region and the soft magnetic properties for Fe–

Al–Ga–P–C–B glassy alloys with various Fe concentrations and possibility of producing a thick glassy alloy sheet with good soft magnetic properties.

Multicomponent $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ ($x=0-4$) and $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$ ($x=0-3$) alloys were used in the present study because the highest permeability (μ_e) at 1 kHz and the largest saturation magnetization (σ_s) for alloys having a supercooled liquid region in the Fe–Al–Ga–P–C–B system were obtained for $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65}\text{C}_{5.75}\text{B}_{4.6}$ and $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11}\text{C}_5\text{B}_4$, respectively.¹⁷ The alloy ingots were prepared by induction melting the mixtures of pure Fe, Al, and Ga metals, premelted Fe–P and Fe–C and pure crystalline boron in an argon atmosphere. Rapidly solidified alloy sheets with various thicknesses ranging from 15 to 320 μm were prepared, through the control of roll velocity, by a single roll melt spinning method. The amorphous nature was confirmed by x-ray diffraction. The thermal stability associated with the glass transition, the supercooled liquid region and crystallization were examined by differential scanning calorimetry (DSC) of a heating rate of 0.67 K/s. The magnetic properties: saturation magnetization (σ_s), coercive force (H_c), permeability (μ_e) at 1 kHz, saturation magnetostriction (λ_s) and core loss (W) were measured at room temperature with a vibrating sample magnetometer (VSM), a B – H loop tracer, an impedance analyzer, a three-terminal capacitance apparatus and a single sheet tester (SST), respectively.

Figure 1 shows the DSC curves for the melt-spun $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ ($x=0-4$) and $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$ ($x=0-3$) alloy sheets with a thickness of about 30 μm as a function of Si content. One can see an increase in specific heat (endothermic reaction) due to a glass transition, followed by a supercooled liquid region for the samples containing $x=0$ to 3 at. % for

FIG. 1. Changes in DSC curves for the $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ and $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$ alloy sheets with a thickness of about $30\text{ }\mu\text{m}$ as a function of Si content.

$\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ and $x=0\text{ at. }\%$ for $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$ and then an exothermic reaction, indicating that crystallization of the amorphous phase takes place through a single stage. The latter leads to simultaneous precipitation of more than two kinds of crystalline phase, including $\alpha\text{-Fe}$, Fe_3B , Fe_3P , Fe_2B , and Fe_3C . A supercooled liquid region and two exothermic peaks due to the two-stage crystallization are observed for the samples containing 4 at. % Si for $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ and $\geq 2\text{ at. }\%$ Si for the $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$. The first and second peaks are due to the crystallization of $\alpha\text{-Fe}$ and Fe_3B and of Fe_3P , Fe_2B and Fe_3C for both alloy series.

Figures 2(a) and 2(b) plot the ΔT_x and t_{max} as a function of Si content. The ΔT_x increases with increasing Si content up to 3 at. % for $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ and up to 2.6 at. % for $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$, then decreases rapidly. There is a clear tendency for t_{max} to increase with increasing ΔT_x .

Figure 3 shows the relation between the ratio of ΔT_x to ΔT_x at $x=0\text{ at. }\%$ ($\Delta T_x/\Delta T_x(\text{Si}=0\text{ at. }\%)$) and the ratio of Si content to total Si and P content ($\text{Si}/(\text{Si}+\text{P})$). The $\Delta T_x/\Delta T_x(\text{Si}=0\text{ at. }\%)$ increases with increasing $\text{Si}/(\text{Si}+\text{P})$, and reaches the maximum value at $\text{Si}/(\text{Si}+\text{P})=24\%$, then decreases with increasing ($\text{Si}/(\text{Si}+\text{P})$) for both alloy series. This fact indicates that the replacement of P by Si as $\text{Si}/(\text{Si}+\text{P})=24\%$ causes the greatest increase in ΔT_x and t_{max} for Fe-Ga-Al-P-C-B-Si glassy alloys.

It is important to achieve high thermal stability of the supercooled liquid for increase in the glass forming ability. That is, the necessity of long-range rearrangements of the constituent elements causes the retardation of the crystallization reaction, leading to the high stability of the supercooled liquid region and the large glass forming ability. It is therefore presumed that the atomic rearrangements are most difficult in case of $\text{Si}/(\text{Si}+\text{P})=24\%$ for these alloys. The atomic sizes of the metalloids change in the order $\text{Si}>\text{P}>\text{B}>\text{C}$. The increase in the variety of atomic sizes also implies that the atomic rearrangement for the precipitation reaction becomes difficult. Furthermore, the similarity of the atomic sizes and the large negative heats of mixing¹⁸ between P and Si allow us to presume that Si is preferentially dissolved into Fe_3P and the precipitation of the $\text{Fe}_3(\text{P}, \text{Si})$ phase becomes more

FIG. 2. The changes of (a) the ΔT_x and (b) the t_{max} for the $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ and $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$ alloy sheets with a thickness of about $30\text{ }\mu\text{m}$ as a function of Si content.

difficult as a results of the need for the rearrangements of two kinds of metalloid atoms. This mechanism is thought to cause the most effective extension of the supercooled liquid region when the P element in these glassy alloys is replaced by Si such that $\text{Si}/(\text{Si}+\text{P})=24\%$.

Figures 4(a), 4(b), and 4(c) show the dependence of H_c , μ_e and λ_s on Si content for $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ and $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$ glassy alloys for a sample thickness of $30\text{ }\mu\text{m}$. The H_c of these glassy alloys are below 3 A/m up to 3 at. % Si for $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ and up to 2.6 at. % Si for $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$. On the other hand, the H_c drastically increases beyond 3 at. % Si and 2.6 at. % Si, respectively, for the two systems. The μ_e increases with increasing Si content up to 3 at. % Si for $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ and up to 2.6 at. % Si for $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$, then decreases for higher Si contents. The influence of Si addition on H_c and μ_e is not reflected in the data for λ_s , and may be related to the glass forming ability. It is, therefore, speculated that the alloys of higher glass forming ability have a more homogeneous structure thus giving superior soft magnetic properties. A detailed investigation of the microstructure is expected to shed some light on the reason for the effect of Si addition on the soft magnetic properties.

FIG. 3. The relation between the ratio of ΔT_x to ΔT_x at Si free ($\Delta T_x/\Delta T_x(\text{Si}=0\text{ at. }\%)$) and the ratio of Si content total Si and P content ($\text{Si}/(\text{Si}+\text{P})$).

FIG. 4. The influence of Si content on (a) H_c , (b) μ_e and (c) λ_s for the $\text{Fe}_{70}\text{Al}_5\text{Ga}_2\text{P}_{12.65-x}\text{C}_{5.75}\text{B}_{4.6}\text{Si}_x$ and $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{11-x}\text{C}_5\text{B}_4\text{Si}_x$ alloy sheets with a thickness of about 30 μm .

Figure 5 shows the changes in core losses at $f=50$ Hz and $B_m=1.0$ T as a function of sample thickness for $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{8.4}\text{C}_5\text{B}_4\text{Si}_{2.6}$ glassy alloy and amorphous $\text{Fe}_{78}\text{Si}_9\text{B}_{13}$ alloy. The structure of both samples confirmed by x-ray diffractometry are also shown in Fig. 5. The core loss for the $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{8.4}\text{C}_5\text{B}_4\text{Si}_{2.6}$ is under 0.3 W/kg at the thickness up to 210 μm . However, that for amorphous $\text{Fe}_{78}\text{Si}_9\text{B}_{13}$ alloy is over 0.3 W/kg at the thickness over 70 μm , and rapidly increase over 100 μm , because of precipitation of Fe_3B crystalline phase. It is well known that the precipitation of crystalline makes the soft magnetic proper-

FIG. 5. Changes in core losses at $f=50$ Hz and $B_m=1.0$ T as a function of sample thickness for $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{8.4}\text{C}_5\text{B}_4\text{Si}_{2.6}$ glassy alloy and amorphous $\text{Fe}_{78}\text{Si}_9\text{B}_{13}$ alloy. The structure of both sample confirmed by x-ray diffractometry are also shown.

FIG. 6. Changes in core losses at 50 Hz for $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{8.4}\text{C}_5\text{B}_4\text{Si}_{2.6}$ alloy sheet, $\text{Fe}_{78}\text{Si}_9\text{B}_{13}$ amorphous ribbon and 6.5% Si-steel with a thickness of about 100 μm as a function of B_m .

ties inferior.¹⁹ Therefore, it can be said that the amorphousness of Fe–Al–Ga–P–C–B–Si glassy alloy is much higher than that of amorphous Fe–Si–B alloy.

Figure 6 shows the core losses at 50 Hz for $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{8.4}\text{C}_5\text{B}_4\text{Si}_{2.6}$ glassy alloy, amorphous $\text{Fe}_{78}\text{Si}_9\text{B}_{13}$ alloy and for 6.5% silicon steel,²⁰ having in each case a thickness of 100 μm , as a function of maximum magnetic flux density (B_m). The core loss for $\text{Fe}_{77}\text{Al}_{2.14}\text{Ga}_{0.86}\text{P}_{8.4}\text{C}_5\text{B}_4\text{Si}_{2.6}$ glassy alloy is much lower than those of other magnetic alloys for the whole range of B_m . Viewed in this light, Fe–Al–Ga–P–C–B glassy alloys containing Si can be regarded as having good potential as bulk soft magnetic materials.

We have developed a choke coil made of new nanocrystalline soft magnetic Fe-M-B (M=Zr, Nb) alloys ("NANOPERM™" material) which exhibit high saturation magnetic induction (B_s), above 1.5 T, excellent soft magnetic properties and zero magnetostriction. A choke coil made of NANOPERM™ material exhibits good dc bias characteristics of inductance because of the high B_s . Furthermore, the choke coil made from NANOPERM™ material showed 1/3rd the temperature rise shown by a core made from Fe-Si-B amorphous alloy. The low core loss and high B_s of NANOPERM™ material allow the reduction of the core size. It is concluded that NANOPERM™ is suitable as a core material for choke coils. © 1998 American Institute of Physics. [S0021-8979(98)36611-6]

I. INTRODUCTION

In increasing instances the reactors of phase modifying equipment are disabled by line current which contains higher harmonic distortion generated by switching regulators, etc. Line current correction to sinusoidal wave by using active filters is a useful method to prevent distortion in the reactors. High saturation magnetic induction (B_s) and low core loss are required for the core material of choke coils as active filters because high frequency current with large amplitude superimposed on direct current flows into the choke coil. It has been reported by us that new nanocrystalline soft magnetic Fe-M-B (M=Zr, Nb) alloys ("NANOPERM™" material) show high B_s above 1.5 T, excellent soft magnetic properties, low core losses and sufficiently small magnetostriction.¹⁻⁴ Figure 1 shows the relation between B_s and permeability (μ_e) at 1 kHz for NANOPERM™ material and other soft magnetic materials. NANOPERM™ material is found to be situated in the top right corner of the figure. NANOPERM™ material is therefore expected to be used as core material for choke coils as active filters. In this article, we report the characteristics of the choke coil made of NANOPERM™ material.

II. EXPERIMENTAL PROCEDURE

The $\text{Fe}_{84}\text{Zr}_{3.5}\text{Nb}_{3.5}\text{B}_8\text{Cu}_1$ alloy was selected an example of NANOPERM™ material in this study. The NANOPERM™ ribbon with 20 μm in thickness was produced by using a single-roller melt-spinning method in an Ar atmosphere. In order to compare the magnetic properties, a commercial $\text{Fe}_{78}\text{Si}_9\text{B}_{13}$ amorphous alloy (METGLAS® alloy 2605 S-2) ribbon with the same thickness as the NANOPERM™ material was prepared. Table I shows typical magnetic properties for the alloys.^{3,6}

Toroidal samples were prepared as follows. A mixture of MgO powders and sodium silica solution (water glass) was applied to both sides of the ribbons to prevent electrical contact between the ribbons. The ribbons were wound into toroidal

cores with 38 mm in outer diameter, 23 mm in inner diameter and 15 mm in height. The annealing treatment of the cores was carried out in vacuum by keeping the cores at 953 K for 600 s (NANOPERM™) or at 643 K for 7.2 ks (Fe-Si-B amorphous alloy). The annealed cores were encapsulation in an epoxy resin. Then the cores were processed by cutting a 2 mm air gap and inserting an insulating material in the gap.

Measurements of core losses were carried out using an ac B - H analyzer after annealing, after encapsulation, and after introducing an air gap. dc bias characteristics were measured after introducing an air gap.

III. RESULTS AND DISCUSSION

Table II shows the size, the lamination factor and the effective cross section of the cores. The size of the cores is almost the same. Figure 2 shows the change in core loss of the cores after annealing, encapsulation, and introducing an

FIG. 1. Relationship between B_s and μ_e at 1 kHz for NANOPERM™, the nanocrystalline Fe-Si-B-Nb-Cu alloys (Ref. 5) and conventional soft magnetic materials.

Alloys	$B_s(T)$	$ \mu $		W (W/kg)		$\lambda_s(10^{-6})$
		1 kHz	100 kHz	1 kHz, 1 T	100 kHz, 0.1 T	
NANOPERM™	1.53	100 000	18 000	1.1	15	~0
Fe-Si-B amorphous alloy	1.56	10 000	5 000	4.0	48	+27

TABLE II. Outer diameter (OD), inner diameter (ID), height (H), lamination factor (K), and effective cross section (S).

Alloys	OD (mm)	ID (mm)	H (mm)	K (%)	S (mm ²)
NANOPERM™	37.1	23.2	15.5	77.1	79.0
Fe-Si-B amorphous alloy	36.9	22.9	15.5	65.8	71.4

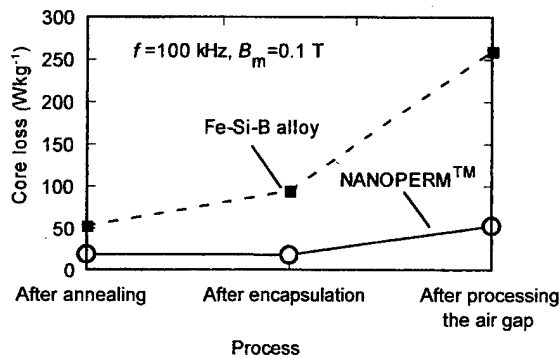

FIG. 2. Change in the core loss of the cores with annealing, encapsulation, and processing the air gap.

FIG. 3. Change of inductance as a function of dc bias current (I_{dc}) times number of turns (N) for choke coils made of NANOPERM™ and Fe-Si-B alloy.

air gap. The core loss of NANOPERM™ core after annealing is about 1/3rd as large as that of the Fe-Si-B core. After encapsulation in the epoxy resin, the core loss of the Fe-Si-B core showed a large increase due to stress from the resin. Since the magnetostriction of the Fe-Si-B amorphous alloy is large, the soft magnetic properties are inferior in the stressed state. On the other hand, the NANOPERM™ core exhibits almost the same low core loss value as that of the core before encapsulation because of its zero magnetostriction. The encapsulation treatment is necessary to cut an air gap. It can be said that the zero magnetostriction is necessary for the toroidal core with a gap to exhibit a low core loss. After introducing an air gap, the core loss increase in both NANOPERM™ and Fe-Si-B alloys. However, the NANOPERM™ core exhibits smaller core loss which is only 1/5th that of the Fe-Si-B core.

Figure 3 shows dc bias characteristics of the gapped cores with 25 turn coil. The inductance of the NANOPERM™ and the Fe-Si-B cores show a decrease around $N \times I = 700$ AT because the saturation magnetic inductions of both the core materials are almost equal. When leakage flux from the air gap can be neglected, inductance (L) of the gapped core can be written as

$$L = N^2 S / \left(\frac{l - l_g}{\mu} + \frac{l_g}{\mu_0} \right), \quad (1)$$

where l_g is gap length, l is length of magnetic path, μ is permeability of material, and μ_0 is permeability of vacuum. When μ is much larger than μ_0 , a term of $(l - l_g)/\mu$ can be neglected. Therefore, the inductance of the gapped core is independent of μ . However, although the NANOPERM™ and the Fe-Si-B cores have the same size and the same gap length, the inductance of the NANOPERM™ core is 10% larger than that of the Fe-Si-B core at a dc bias current of zero. The difference in inductances is caused by the difference in effective cross sections of the cores. As shown in Table II, the effective cross section of the NANOPERM™ core is 14% larger than that of the Fe-Si-B core, which is in good agreement with the difference in inductances.

Next, we have examined the relation between the choke coil loss and temperature rise (ΔT) of the choke cores. The miniaturization of the core is limited by B_s and by the core loss of the core material. If the core loss is large, the core volume should be increased because maximum magnetic induction (B_m) should be decreased to reduce ΔT . Figure 4 shows the B_m dependence of the choke coil loss which consists of the core loss and the copper loss. The operating frequency is 50 kHz and B_m is changed from 0.01 to 0.1 T. The choke coil loss is 4.2 W for Fe-Si-B alloy, and is 1.3 W for

FIG. 4. B_m dependence of the choke coil loss, which consists of the core loss and the copper loss.

FIG. 5. ΔT of the choke coils as a function of B_m .

NANOPERM™ material at $B_m = 0.1$ T. Figure 5 shows ΔT of the choke coils as a function of B_m . When $B_m = 0.1$ T, ΔT is 34 K for the Fe-Si-B choke coil and 11 K for the NANOPERM™ choke coil, respectively. The ΔT of the NANOPERM™ choke coil is only 32% that of the Fe-Si-B one. In order to achieve a small ΔT of 11 K for Fe-Si-B core, it is necessary to reduce the B_m value to 0.05 T. This means that core volume should be doubled for the Fe-Si-B choke coil.

NANOPERM™ shows a high B_s which is comparable to that of Fe-Si-B amorphous alloys and its choke coil loss is only 1/3rd that of Fe-Si-B amorphous alloys. The very low loss allows a reduction in core size. It is concluded that the

size of the choke coils can be significantly reduced by replacing the core material from Fe-Si-B amorphous alloys to NANOPERM™. Therefore, NANOPERM™ material is suitable as core material for the choke coils of active filters.

The effects of Al on the magnetic properties of nanocrystalline $\text{Fe}_{73.5-X}\text{Al}_X\text{Si}_{13.5}\text{B}_9\text{Cu}_1\text{Nb}_3$ alloy ribbons, where $0 \leq X \leq 10$, are reported for the first time. The evolution of the structure and magnetic properties of the ribbons, which were initially cast into the amorphous state in an inert gas environment at subatmospheric pressure, were studied as a function of annealing temperature T_{ann} . The minimum dc coercivity developed during annealing, H_c^{min} , was found to decrease significantly with increasing Al content from 0.5 A/m at $X=0$ to 0.3 A/m at $X=2$ and to remain at approximately this level over the range $2 < X \leq 8$ before rising to 0.4 A/m at $X=10$. The saturation polarization, J_s , was, however, found to decrease linearly over this range from $J_s=1.5$ T at $X=0$ to $J_s=0.9$ T at $X=10$ for samples exhibiting H_c^{min} . As there was little significant reduction in the mean crystallite size, d_g , at H_c^{min} with increasing X , this decrease in coercivity was considered to result from a reduction of the magnetocrystalline anisotropy, K_1 , of the crystallites as a result of the incorporation of Al. © 1998 American Institute of Physics. I. INTRODUCTION

Nearly a decade ago Yoshizawa *et al.*¹ of Hitachi Research Laboratories showed that small additions of Nb and Cu to a base FeBSi glass forming composition induce the initially amorphous as-spun ribbon to devitrify, on controlled annealing, to a nanocomposite structure of FeSi crystallites, of mean diameter 10–15 nm in a glassy matrix which is enriched in Nb and B. The Cu and Nb act, respectively, to maximize the number density of crystal nuclei and to retard grain growth, thus promoting the formation of an ultrafine grain structure. Contrary to classical behavior of pinning of domains at grain boundaries, for grain diameters (d_g) ≤ 50 nm the coercivity H_c diminishes with decreasing d_g down to $\sim 0.5 \text{ Am}^{-1}$ at ~ 10 nm while, correspondingly, the initial permeability μ_i increases to a peak value of $\sim 10^5$. These properties are better than for amorphous Fe-based alloys and are comparable with those of Co-based metallic glasses which has significant technoeconomic significance. Thus, this so-called Finemet® alloy has stimulated the curiosity of a large body of magnetic and materials scientists.

A number of workers have investigated the effects on the soft magnetic properties of the substitution of additional alloying elements for Fe in the $\text{Fe}_{73.5}\text{Si}_{13.5}\text{B}_9\text{Cu}_1\text{Nb}_3$ alloy composition to further improve the properties [e.g., Co,² Al³] as well as the substitution of Cr, V, Ta, etc., for Nb.⁴ No significant improvements in soft magnetic properties were reported over those of the base composition with the exception of the study of Lim *et al.*³ which found that substitution

of Al for Fe in $\text{Fe}_{73.5-X}\text{Al}_X\text{Si}_{13.5}\text{B}_9\text{Cu}_1\text{Nb}_3$ in the range $0 \leq X \leq 1$ improved the dc coercivity (H_c) but caused other soft magnetic properties, i.e., relative ac permeability (μ) and saturation magnetostriction (λ_s) to deteriorate. In this article we present initial data from an extensive study of $\text{Fe}_{73.5-X}\text{Al}_X\text{Si}_{13.5}\text{B}_9\text{Cu}_1\text{Nb}_3$ with $0 \leq X \leq 10$. The rationale behind this work is that ternary FeSiAl crystals exhibit lower K_1 than those of the binary FeSi system and that the saturation magnetostriction λ_s of the nanocrystallites can be readily controlled⁵ thus leading to the possibility of the development of alloys with lower λ_s than Finemet®.

II. EXPERIMENT

A series of $\text{Fe}_{73.5-X}\text{Al}_X\text{Si}_{13.5}\text{B}_9\text{Cu}_1\text{Nb}_3$ alloy ingots with compositions in the range $0 \leq X \leq 10$ were prepared by rf melting of high purity elements in a flowing Ar atmosphere. Ribbons of cross section typically $20 \mu\text{m} \times 2.0 \text{ mm}$ and surface roughness less than $1.5 \mu\text{m}$ were prepared by melt spinning these ingots in helium at 1/3 atm ambient pressure. The resultant ribbons were cut into 100 mm lengths and thermal treatments were performed in an inert Ar atmosphere in a conventional furnace for 1 h after which the samples were allowed to air cool. The structure of the alloys, both in the as-cast state and after subsequent heat treatment, was confirmed by x-ray diffraction using Co $K\alpha$ radiation, and the mean crystallite size (d_g) for the Fe-Si phase estimated from the half peak breadth of the (110) x-ray diffraction peak via the Scherrer equation. TEM was also employed for selective studies of the nanostructure and grain size. The saturation polarization (J_s), H_c , and λ_s were measured using a vibrating sample magnetometer (VSM) hysteresis loop

tracer⁶ and the small angle magnetisation rotation (SAMR) method,⁷ respectively. The loop tracer has been specifically designed for reliable and reproducible measurements of high μ low H_c materials.

III. RESULTS AND DISCUSSION

The results presented in this section are for samples heat treated at an optimum annealing temperature ($T_{\text{ann}}^{\text{opt}}$) to develop the minimum dc coercivity H_c^{\min} for each of the compositions investigated. This was found to be 540 °C for $X=0$ and 520 °C for all of the Al-containing compositions. Figure 1(a) shows the dependence of minimum coercivity H_c^{\min} as a function of Al substitution X. Following a substantial (40%) initial decrease, from 0.5 A/m at $X=0$ to 0.3 A/m for $X=2$, H_c^{\min} remains approximately constant at 0.3 A/m up to $X=8$ at. %; it then increases to 0.4 A/m at $X=10$ at. %. The effect of substituting Fe for Al on the magnitude of J_s can be seen in Fig. 1(b). The linear decrease in J_s , from 1.5

FIG. 2. Variation in the effective anisotropy $\langle K \rangle$, derived from Eq. (2), as a function of the aluminum content X of the alloys.

T for the base composition to 0.9 T at $X=10$ (a rate of ~ 0.06 T/at. % Al) is as might be expected for replacement of Fe by a nonferromagnetic component. Figure 1(c) shows that the aluminium content does not influence significantly the mean crystallite diameter for alloys in their optimum condition, i.e., d_g remains constant at 10 ± 1 nm. This was also confirmed by direct observation of the alloy nanostructure by TEM. This observation contrasts with that of Lim *et al.*³ who reported d_g to decrease upon the addition of 0.1 at. % Al and to remain constant thereafter although the magnitude of this decrease was not disclosed.

These values of H_c^{\min} and J_s allow the variation in effective magnetocrystalline anisotropy $\langle K \rangle$ to be estimated as a function of X. By using the random anisotropy model (RAM) developed by Alben *et al.*⁸ for amorphous ferromagnets Herzer⁹ showed that, for d_g less than the exchange length L_{ex} (~ 40 nm), $\langle K \rangle$ could be approximated by

$$\langle K \rangle \approx K_1^4 d_g^6 / A^3 \quad (1)$$

and that H_c and $\langle K \rangle$ were related thus

$$H_c = p_c \times \frac{\langle K \rangle}{J_s} \quad (2)$$

which leads to the following relationship between coercivity and grain diameter:

$$H_c \approx p_c \times \frac{K_1^4 d_g^6}{A^3 J_s}, \quad (3)$$

where p_c is a constant and A is the exchange stiffness inside the crystal with all other symbols as previously defined. Assuming⁹ that the composition of the crystallites is Fe \sim 20 at. % Si and $A = 1 \times 10^{-11}$ J m⁻¹ and $K_1 = 8 \times 10^3$ J m⁻³ and using the measured values of H_c^{\min} , J_s and d_g for the $X=0$ alloy in Eq. (3) yields a value of 0.19 for the constant p_c . Assuming that this value is applicable for the range of aluminium contents studied we can use the experimentally determined values of H_c^{\min} and J_s to estimate $\langle K \rangle$ from Eq. (2). The variation in $\langle K \rangle$ with respect to X, derived in this way, is shown in Fig. 2.

Equation (1) shows $\langle K \rangle$ to be strongly dependent upon both d_g and K_1 and, as such, both of these factors must be

FIG. 3. Variation in the saturation magnetostriction (λ_s) as a function of alloy aluminium content, X .

considered as possible reasons for the observed decrease. $\langle K \rangle$ varies as a d_g^6 so that a 1 nm decrease in d_g could account for the change in $\langle K \rangle$ shown in Fig. 2. As ± 1 nm is estimated to be the precision of the x-ray line broadening determination of d_g it cannot be stated, on this basis, that it is the principal contribution to the decrease in $\langle K \rangle$. However, although it is difficult to establish the absolute value of d_g to better than ± 1 nm by TEM owing to crystallite overlapping effects in the thin foil image, the observations indicated that no change occurred over the range of X studied and thus it is considered that the observed decrease in H_c^{\min} result primarily from a decrease in the magnetocrystalline anisotropy K_1 .

The measured magnetostriction of the Al-alloys exhibiting minimum dc coercivity (Fig. 3) is significantly greater than that of the Al-free alloy, measured at optimum H_c , rising to a maximum of 10×10^{-6} at $X=2$ from 3×10^{-6} at $X=0$ and falling as X increases further to a value of $\lambda_s = 6 \times 10^{-6}$ in the range of $4 \leq X \leq 10$ and are in good agreement with the results of Lim *et al.*³ for $0 \leq X \leq 1$. Figure 4 compares the dependence on annealing temperature of λ_s for the $X=2$ alloy of the present work and those of Yoshizawa *et al.*¹ for the Finemet® composition. Clearly λ_s is very sensitive to T_{ann} in both alloys. In the case of the alloy containing 2 at. % Al, for example, λ_s falls to approximately zero after annealing at 550 °C for 1 h which is significantly smaller than the minimum value of 2.1×10^{-6} developed by the Al-free composition.¹ An advantage of the Al containing alloys is that an ultralow coercivity is developed over a wider range of annealing temperatures than is the case for the Al-free composition, meaning that, if the $X=2$ alloy is optimized with respect to magnetostriction, for example, the coercivity exhibited in this condition is comparable with that of Finemet, i.e., $H_c = 0.5$ A/m.

FIG. 4. Comparison of the response of saturation magnetostriction (λ_s) to annealing temperature (T_{ann}) for $X=0$ (Ref. 1) and $X=2$ (present work).

IV. CONCLUSIONS

The soft magnetic properties of nanocrystalline $\text{Fe}_{73.5-X}\text{Al}_X\text{Si}_{13.5}\text{B}_9\text{Cu}_1\text{Nb}_3$ have been investigated in the range of $0 \leq X \leq 10$. It was found that the minimum dc coercivity developed on annealing of the initially amorphous as-spun ribbons showed an initial decrease from 0.5 A/m at $X=0$ to 0.3 A/m at $X=2$ after which H_c^{\min} shows little variation up to $X=8$ beyond which it increases to 0.4 A/m at $X=10$. Over this same range of X the saturation polarization decreases linearly while d_g was determined by x-ray methods to remain at a constant 10 ± 1 nm and TEM confirmed that there was no change in the structure with increasing aluminium substitution. The saturation magnetostriction shows a marked increase over this range of X compared with the base alloy composition. The improvement in the dc coercivity has been attributed to a decrease in the effective anisotropy $\langle K \rangle$ of the alloy and this decrease has been ascribed, on the basis of available evidence, to a decrease in the magnetocrystalline anisotropy of the nanocrystallites. We have also established that, by the optimization of the heat treatment temperature for the $X=2$ material a zero magnetostrictive alloy with a dc coercivity comparable with that of Finemet is achieved.

Results are presented on the evolution with the thermal treatment parameters of the effective anisotropy and dispersion fields and of the saturation magnetostriction of samples having nominal compositions given by $\text{Fe}_{93-x}\text{Zr}_7\text{B}_x\text{Cu}_y$ ($x=6-8$ and $y=0-2$). From these data we conclude that the enhancement of the soft magnetic character of the samples induced by the anneals carried out in the temperature range 480–600 °C could be linked both to the decrease of the anisotropy field and to the reduced magnetostriction values resulting from the thermal treatments. © 1998 American Institute of Physics. I. INTRODUCTION

$\text{FeZrB}(\text{Cu})$ crystalline alloys with ultrafine microstructures show excellent soft magnetic properties and are regarded as promising candidates for practical uses. These alloys are prepared by partial crystallization of melt spun precursors resulting in the precipitation, from the amorphous matrix, of bcc Fe grains having a typical diameter of 10 nm.¹ The basic mechanism responsible for the outstanding magnetic properties of these nanocrystalline alloys is the averaging (over regions containing a large number of grains) of the easy directions of the local magnetocrystalline anisotropy.² From a study of the effective anisotropy in FINEMET-type nanocrystalline alloys,³ it was possible to deduce that this averaging was based on the occurrence of intergranular coupling. It was also possible to evaluate the typical dimensions of the coupled units. Nevertheless, and since the reduction of the magnetic anisotropy from the value obtained in the amorphous precursor down to that obtained in the nanocrystalline alloy was not sufficient to account for the reduction of the coercive force accompanying the nanocrystallization, the enhancement of the magnetic softness was proposed to be also linked to the decrease of the microstructure–magnetization interactions.³ On the basis of these interactions there is the magnetoelastic coupling, and therefore, a reduced magnetostriction value is considered to be a crucial property to achieve extremely soft magnetic behavior.

In the present work, we report on the dependence of the effective magnetic anisotropy on the annealing temperature for nanocrystalline $\text{FeZrB}(\text{Cu})$ alloys. Our results will be correlated with the evolution of the saturation magnetostriction, λ_s , during heat treatment.

II. PREPARATION OF SAMPLES AND EXPERIMENTAL TECHNIQUES

Amorphous alloys of nominal compositions $\text{Fe}_{93-x}\text{Zr}_7\text{B}_x\text{Cu}_y$ ($x=6-8$ and $y=0-2$) were prepared by

the single-roller melt-spinning method and were annealed under an Ar atmosphere for 1 h at temperatures ranging from 480 up to 650 °C.

The anisotropy field, H_k , associated with the effective anisotropy, K_{eff} , and the dispersion field, H_d , associated with the inhomogeneities of the magnetization distribution, were determined, both in the as-quenched and the treated samples, from measurements of the transverse biased initial

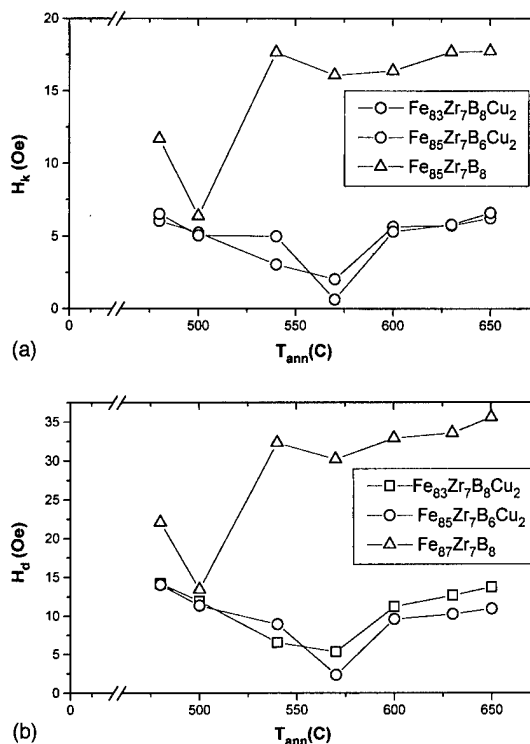

FIG. 1. (a) Temperature dependence of the anisotropy field of the samples. (b) Temperature dependence of the dispersion field of the samples.

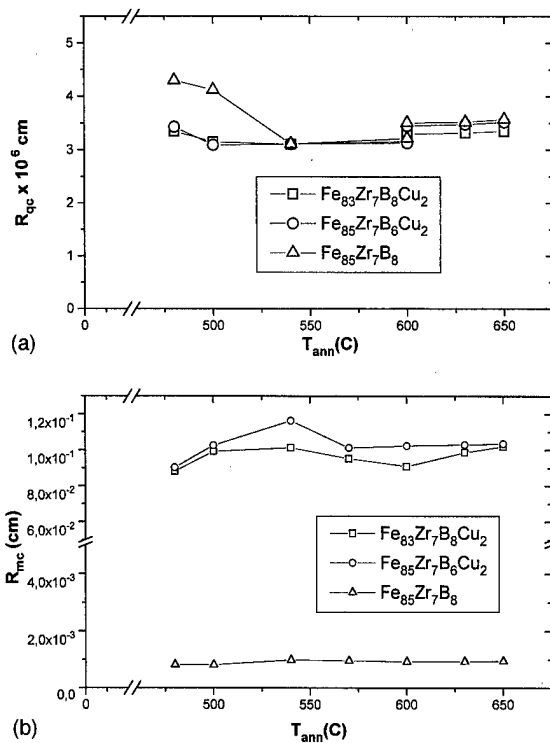

FIG. 2. (a) Temperature dependence of the R_{qc} parameter. (b) Temperature dependence of the R_{mc} parameter in the studied samples.

susceptibility, χ_t .³ For that purpose the original ribbons (3 mm wide, 20 mm thick) were cut by acid etching into disks having diameter 3 mm.

The transverse biased initial susceptibility, χ_t , was measured by applying simultaneously a saturating dc field, H_1 , along the directions of the easy and hard axes of the effective anisotropy and a small ac field, H_2 , directed perpendicular to H_1 . We measured the magnetization component parallel to H_2 . The transverse biased initial susceptibility can be written as

$$1/X_t = H_{\text{eff}}/M_s, \quad (1)$$

where M_s is the saturation magnetization and H_{eff} is given by

$$H_{\text{eff}} = H_1 + (-)H_k + H_d. \quad (2)$$

In (2) the plus (minus) signs stand for the cases in which the saturating field is applied along the easy (hard) axes. In order to identify the macroscopic easy (hard) axis of our samples, the transverse biased initial susceptibility was measured in all of them by applying the saturating field along different in-plane directions. The saturation magnetostriction was measured, at room temperature, by means of the strain modulated ferromagnetic resonance (SMFMR) method with the magnetic field parallel to the ribbon plane.

III. RESULTS

Figures 1(a) and 1(b) show the treatment temperature, T_{ann} , dependence of H_k and H_d , respectively, corresponding to all the samples studied. From our results it is apparent that the anisotropy field exhibited a minimum value (occurring at

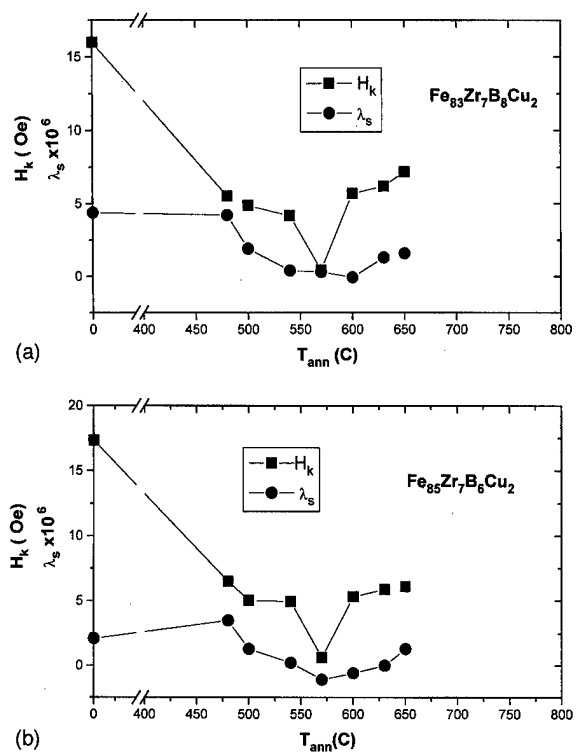

FIG. 3. (a) and (b) Temperature dependence of the anisotropy field and the saturation magnetostriction of the Cu-containing samples.

temperatures coinciding with those of the onset of the crystallization process). The minima measured in the Cu-containing samples coincide at 570 °C whereas that corresponding to the Cu-free sample is observed at 500 °C. Regarding the H_d results, it is important to remark that this parameter shows minima at temperatures coinciding with those observed in the $H_k(T_{\text{ann}})$ curves. The very small H_d value obtained in the Cu-containing samples could result from strong intergranular exchange coupling promoted by a high degree of homogeneity of the grain size distribution.

The micromagnetic analysis of the transverse biased initial susceptibility results, allows a further quantification of the coupling between the microstructure and the magnetization. According to Hoffmann,⁴ the minor, R_{qc} , and major, R_{mc} , semiaxis of the elliptical regions in which the magnetization is coupled, resulting in a reduction of the effective anisotropy, can be expressed as

$$R_{qc} = [AH_k/K_{\text{eff}}(H_1 + (-)H_k)] \quad (3)$$

and

$$R_{mc} = 2^{3/2}d^{1/2}A^{1/4}K_{\text{eff}}^{3/4}M_s[H_k(H_1 + (-)H_k)], \quad (4)$$

where A is the exchange constant, H_1 is the saturating field (our data were evaluated for an H_1 value corresponding to $30H_k$), and d is the thickness of the samples. In Figs. 2(a) and 2(b) we present the annealing temperature dependence of R_{qc} and R_{mc} measured in the heat treated samples. Our results are almost independent of the annealing parameters and composition, except for the fact that the R_{mc} values obtained in the Cu-containing samples are two orders of magnitude larger than those measured in the Cu-free sample. This result clearly shows that the intergranular exchange coupling, that

induces anisotropy averaging, is not the only source of the magnetic softening for these samples. In order to check the influence of the magnetoelastic coupling, we present in Figs. 3(a) and 3(b) the evolution of the saturation magnetostriction constant with heat treatment temperature and, for the sake of comparison, that of the anisotropy field. As can be seen in these figures, the saturation magnetostriction decreases down to a minimum value coinciding with the minimum of the anisotropy field. Since these decreases take place simultaneously with the bcc Fe precipitation, the soft magnetic character should be related to the two-phase nature of the partly crystallized samples.

IV. CONCLUSIONS

The enhancement of the soft magnetic properties in the FeZrB(Cu) alloys occurs due to the combination of two factors both of them associated with the onset of the nanocrys-

tallization process: the low values of the effective anisotropy field and the decrease of the saturation magnetostriction. The intergranular coupling leading to the anisotropy reduction is clearly favored by the Cu addition, presumably due to the larger number of bcc Fe grains involved in the coupled units, compared with those present in the Cu-free sample. Optimum heat treatment conditions (540 °C, 1 h) result, in the case of the Cu-containing samples, in a large degree of intergranular coupling as evidenced [Figs. 3(a) and 3(b)] by the minimum value of the magnetization inhomogeneities related to the dispersion field.

Approach to the magnetic saturation in nanocrystalline ferromagnets in the random anisotropy model

G. R. Aranda and J. González^{a)}

Departamento de Física de Materiales, Facultad de Químicas, Universidad del País Vasco, 20009 San Sebastián, Spain

K. Kulakowski

Faculty of Physics and Nuclear Techniques, University of Mining and Metallurgy, 30059 Cracow, Poland

Recent experimental data on the magnetization curve $M(H)$ of magnetically soft nanocrystalline $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$ sample are analyzed in terms of the random anisotropy model. Numerical calculations of magnetization are supplemented by a high-field expansion. Near the saturation we get $M(H)/M_s = 1 - 4\langle K \rangle^2 / (15M_s^2 H^2)$, where $\langle K \rangle$ is the averaged anisotropy of crystalline grains, contained in large magnetic domains. Section I is an introduction. In Sec. II, reference data on the model parameters of the nanocrystalline system $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$ are collected in order to justify the model approximations and to prepare the comparison with experimental results. In the two subsequent sections, the results of the calculations are described and discussed. © 1998 American Institute of Physics. [S0021-8979(98)28211-9]

I. INTRODUCTION

Nanocrystalline Fe-based materials are interesting for their superior magnetic softness.¹ A prominent example of these materials is $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$ and their magnetic behavior can be explained by the random anisotropy model.² Their low coercive field (≈ 1 A/m) and high initial permeability ($\approx 10^5$) are related to a new magnetic phase. Moreover, new relations can be deduced^{2,3} between the magnetic properties of the system and its micromagnetic structure.

The shape of the magnetization curve in $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$ was investigated experimentally⁴ both for amorphous and nanocrystalline state. The relevant process of magnetization was the reversible rotation of magnetic moments. The results were fitted to the law

$$M(H) = M_s(1 - a_1/H - a_2/H^2) + bH^{1/2}. \quad (1)$$

The last term in Eq. (1) was responsible for a change of M_s and it was expected to be relevant in very high magnetic fields. The term a_1/H was ascribed to macroscopic inhomogeneities and it was expected to appear for fields below 2 kOe. The constant a_2 is known⁵ to describe the curvature of energy of local magnetic moments at the equilibrium direction. In Ref. 4, a_2 was interpreted as due to magnetoelastic anisotropies of internal stresses. Thus a_2 was expected to be proportional to the squared magnetostriction constant λ_s . This interpretation was based on the theory of stress fields of dislocation dipoles in amorphous systems.^{6,7}

We will demonstrate, that the term $1/H^2$ is a direct consequence of the random anisotropy model.^{2,8}

II. PARAMETERS OF THE NANOCRYSTALLINE SYSTEM

In Ref. 3, the size L_{ex} of magnetic domains in soft magnetic phase of $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$ is of the order of

10^{-6} m, and the density of the magnetic anisotropy energy $\langle K \rangle$ of a magnetic domain is about 2 J/m^3 . So the energy of a virtual thermal excitation of a domain of the order of $\langle K \rangle \times L_{\text{ex}}^3 \approx 12 \text{ eV}$, almost three orders of magnitude larger than the thermal energy at room temperature.

For large domains, magnetic coupling between them is limited to domain surfaces and neglectable. The energy of a domain in its ground state is

$$VE(\theta, \phi) = \langle K \rangle V \sin^2(\theta - \phi) - HM_s V \cos \phi, \quad (2)$$

where $\langle K \rangle$ is the same as above, θ the angle between a local easy axis of a magnetic domain and the applied magnetic field H , ϕ is the angle between the magnetic moment of the domain and the applied field, and V is the domain volume. Minimizing the energy E as a function of ϕ , we get the ground state value ϕ_0 as a function of θ . Macroscopic magnetic moment is the average $\langle \cos \phi_0 \rangle$ over all directions of the local easy axis. To avoid hysteresis and limit our considerations to reversible rotations of local magnetic moments, only positive contribution to magnetization is taken into account.

As we see, at $T=0$ the only relevant parameter of the model is $x = M_s H / \langle K \rangle$.

After Ref. 3 we take M_s to be 1.2 T. For fields $H \approx 2$ kOe we get the Zeeman energy of the order of 10^5 J/m^3 . Note that in Ref. 4, measurements were performed for fields up to 60 kOe. As noted above, the local anisotropy energy for nanocrystalline grains is of the order of 2 J/m^3 . So x for the soft nanocrystalline phase is of the order of 10^5 .

For amorphous as-quenched state, internal stresses around 40 MPa⁹ combined with the magnetostriction $\lambda_s = 20 \times 10^{-6}$ produce anisotropy energy of the order of 800 J/m^3 . Finally, for uncorrelated crystalline grains above the Curie temperature of the amorphous matrix, the local anisotropy energy of the grains is known³ to be about 8000 J/m^3 . In all three cases, we obtain x above ten.

^{a)}Electronic mail: wabroarg@scxol.sc.ehu.es

Does the argument on the ground state of the beginning of this section hold for the as-quenched amorphous state? In this case, the exchange length L_{am} can be evaluated as

$$L_{\text{am}} = \{2A/(3\lambda\sigma)\}^{1/2}, \quad (3)$$

where A is the exchange stiffness of the order of 10^{-11} J/m³. Keeping the above-noted value of 40 MPa for annealed samples, we get $L_{\text{am}} \approx 100$ nm, and the temperature necessary for thermal excitations of amorphous system of the order of $A^{3/2}/k_B/(3\lambda\sigma/2)^{1/2} = 10^5$ K. Obviously, this is much more than the Curie temperature for grains (about 880 K³).

For the turning field H_1 where the $1/H^2$ law starts to be relevant was found to be 1 to 2 kOe nanocrystalline systems. For amorphous ribbons H_1 is known to be 0.3 kOe.

III. CALCULATIONS AND RESULTS

After Eq. (2), with $\epsilon = 1/x$ the condition of the minimum of energy is $\sin \phi_0 = \epsilon \sin[2(\theta - \phi_0)]$. For high magnetic fields, when $x \geq 10$, small ϵ , the angle between the magnetic moment of a domain and the applied magnetic field in the equilibrium, ϕ_0 , is small and can be developed in ϵ powers

$$\phi_0 = \epsilon \sin(2\theta) - \epsilon^2 \sin(2\theta)\cos(2\theta). \quad (4)$$

For $T > 0$, the magnetization $M(H)$ can be written as

$$M(H)/M_s = 1/(2\pi) \int_0^{\pi/2} \sin \theta d\theta \int_0^{2\pi} d\zeta \langle m(\theta, \zeta, T) \rangle, \quad (5)$$

where

$$\langle m(\theta, \zeta, T) \rangle = 1/Z \int_0^{\pi/2} \sin \phi d\phi \int_0^{2\pi} d\psi \cos \phi \times \exp[-\beta V E(\theta, \zeta, \phi, \psi)], \quad (6)$$

the angles θ and ζ denote the direction of a local easy axis, ϕ and ψ denote the direction of a local magnetic moment, and Z is the partition function. For $T = 0$,

$$\exp[-\beta V E(\theta, \zeta, \phi, \psi)] = \delta(\phi - \phi_0) \delta(\psi - \zeta), \quad (7)$$

$$M(H)/M_s = 1/(2\pi) \int_0^{\pi/2} \sin \theta d\theta \int_0^{2\pi} d\zeta \cos \phi_0. \quad (8)$$

Expanding $\cos \phi_0 \approx 1 - \phi_0^2/2$ and substituting $\phi_0 = \epsilon \sin 2\theta$ [see Eq. (4)], we get

$$M(H)/M_s = 1 - 4\epsilon^2/15 = 1 - 4\langle K \rangle^2/(15M_s^2 H^2) \quad (9)$$

which is the $1/H^2$ law, derived for high field and $T = 0$.

A low-temperature approximation is also justifiable for soft nanocrystalline phase. For $T \neq 0$ but very small (Sec. II), the deviations from the ground state are much smaller than the ground state angle ϕ_0 . Thus

$$M(H)/M_s = 1 - 4\langle K \rangle^2/(15M_s^2 H^2) - 3K_B T/(2VM_s H). \quad (10)$$

Equation (10) is valid if $VM_s H \gg V < K \gg K_B T$. As was justified in Sec. II. On the contrary, in the limit $\epsilon \rightarrow 0$, $t \rightarrow \infty$, $t\epsilon = \text{const}$ we get $M(H)/M_s = 1 - t\epsilon + (t\epsilon)^2$. However, this limit is not appropriate for our system.

FIG. 1. The coefficient α , (points) and its numerical error (dotted line), as dependent on the parameter $x = M_s H / \langle K \rangle$.

Numerical calculations on the curve $M(H)$ for zero temperature show that the term $1/H^2$ arises as soon as the value of the parameter $x = M_s H / \langle K \rangle$ exceeds 2.0.

This result can be shown in several different ways. In Fig. 1 we show the value of the exponent α , as defined in $M(H) = M_s(1 - a/H^\alpha)$. In our numerical calculations, $M_s = 1$. The numerical error $\Delta\alpha$ of α is due to the error ΔM of M , and we calculate it from $\Delta\alpha = \Delta(M/M_s) / \{ [1 - (M/M_s)] \ln(H/H_0) \}$, where H_0 is a field unit. This result is included in Fig. 1. ΔM is determined numerically by varying the step of integration, and it is found to be 3×10^{-9} . As can be seen in Fig. 1, the value $\alpha = 2.0$ is the asymptotic one for large values of x . Simultaneously, the numerical error $\Delta\alpha$ exceeds 10^{-4} at $x \approx 200$.

Numerical calculations for $T > 0$ contain triple integration, and the accuracy for $M(T, H)$ is near 10^{-4} . Also, the exponential Gibbs factors in Eq. (6) disable the low temperature range to be investigated numerically. Still, we have made an attempt to evaluate a_1 and a_2 of Eq. (1) as dependent on x for various temperatures. For $T = 0$, the coefficient a_1 is found to be maximal near $x = 1$, and above $x = 3$ its absolute value is less than 2×10^{-2} . The coefficient a_2 increases with x from zero to a maximum value near $x = 2.0$, and then it decreases to about 0.27. Analytical calculations give the asymptotic value $a_2 = 4/15 = 0.266(5)$ for large x [Eq. (10)]. For $T > 0$ the plots of $a_1(x)$ and $a_2(x)$ are smoother. The results are given in Figs. 2(a) and 2(b). Clearly in Fig. 2(b), the coefficient a_2 is close to a constant. Numerical calculations for a_1 (checked from $t = 0.03$ to 0.066, t being $K_B T / \langle K \rangle V$), yield $a_1 = K_B T / VM_s H$. In Eq. (10), $a_1 = 3K_B T / 2VM_s H$. It is possible that this change of the coefficient occurs in the range of lower temperatures, which cannot be captured numerically.

In Fig. 3, numerical plots are shown of $y = x^2 [1 - M(x)]$ for different temperatures. As we see, the values of y below $x \approx 2$ and the value of x , where the $1/H^2$ law starts to be valid, do not depend on temperature.

IV. DISCUSSION

In the nanocrystalline state, the magnetostriction is known³ to be reduced by at least a factor of 4, if compared

FIG. 2. The coefficients (a) a_1 , (b) a_2 as dependent on x , calculated numerically for various temperatures. Temperature is expressed as $t = k_B T / \langle K \rangle V$. The plots are: (●) $t=0$, (+) $t=0.028$, (○) $t=0.33$, (◆) $t=0.04$, (×) $t=0.05$, and (▽) $t=0.066$. Guide-eye solid line is drawn through the points for $t=0$. Note that for $\langle K \rangle = 2.7 \text{ J/m}^3$ and $V = 10^{-18} \text{ m}^3$ the value $t=0.028$ means that $T=5400 \text{ K}$.

with that for the amorphous matrix. It was pointed out in Ref. 4, that if the coefficient a_2 from Eq. (1) is proportional to the second power of the magnetostriction, it should be much smaller for the nanocrystalline state. Experimental data show that this coefficient is only twice smaller than that for the as-quenched amorphous sample.

We think a_2 for amorphous and nanocrystalline samples are of different origin. In amorphous systems, the fluctuations of local magnetic anisotropy are due to local stresses and the magnetoelastic coupling. On the contrary, in soft nanocrystalline phase the local magnetic anisotropy is due to crystalline grains of bcc-FeSi, and it is partially averaged out within magnetic domains.² The experimental value of a_2 is about $2 \times 10^{-4} \text{ Oe}^2$.⁶ With this result and Eq. (10), we get $\langle K \rangle \approx 2.7 \text{ J/m}^3$, close to the value 2 J/m^3 , accepted for the soft nanocrystalline phase.⁶

FIG. 3. The quantity $x^2[1-M(x)]$ as dependent on x for various temperatures $t = k_B T / \langle K \rangle V$. The plots are: (●) $t=0$, (+) $t=0.028$, (○) $t=0.33$, (◆) $t=0.04$, (×) $t=0.05$, and (▽) $t=0.066$. Guide-eye solid line is drawn through the points for $t=0$.

On the contrary, if we apply Eq. (10) to an amorphous as-quenched system, we get the local anisotropy $3/2 \lambda \langle \sigma \rangle$ near 4 J/m^3 . Keeping $\lambda = 20 \times 10^{-6}$, we get the average amplitude of stress to be about 0.1 MPa , which is more than two orders of magnitude smaller than the values in Ref. 9.

The experimentally observed value of the coefficient a_1 for the soft nanocrystalline phase was 4 to $5 \times 10^{-3} \text{ Oe}$. As it was pointed out in Ref. 3, the origin of the $1/H$ term is due to macroscopic inhomogeneities. Substituting $V = L_{\text{ex}}^3$ into Eq. (10), we get the coefficient a_1 much smaller than the experimental value. The $1/H$ term of Eq. (10), if observed experimentally for nanocrystalline phase, should be only a small correction to the contributions of other effects.

In conclusion, the $1/H^2$ law of approach to the magnetic saturation, which was observed in the soft nanocrystalline phase of $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$, can be entirely assigned to the FeSi crystalline grains. The coefficient a_2 is found to be temperature independent, as it was shown experimentally.

Calculation of magnetostatic fields is usually the most time-consuming stage of micromagnetic simulations. In this article, the Bramble-Pasciak-Xu multilevel preconditioners (MP) are applied to the computation of magnetostatic fields in media such as magnetic tapes or thin films. The asymptotic number of arithmetic operations is optimal and proportional to the number of nodes in the finite element mesh. Unlike the fast Fourier transform, MP are applicable to irregular meshes. Local (adaptive) mesh refinement can be implemented by switching to the hierarchical basis.

I. INTRODUCTION

Magnetization of media in micromagnetic problems is usually simulated by minimizing the sum of the magnetostatic energy, the exchange energy, the anisotropy energy, etc. Calculation of the magnetostatic field is the crucial stage of the overall numerical process of energy minimization. The objective of this study is to develop efficient magnetostatic field algorithms for micromagnetic simulations. The focus is on media such as magnetic tapes or thin films where the nonuniform arrangement of the magnetic particles or grains is of particular interest.

Various linear system solvers are currently in use in magnetostatic finite element (FE) analysis.¹³ The incomplete Cholesky conjugate gradient (ICCG) method⁹ is probably the most popular among iterative methods. Direct methods, such as nested dissection⁵ (ND) or quotient minimum degree,⁵ for two-dimensional (2D) problems are usually faster¹³ and more robust than ICCG. Linear 2D magnetostatic problems of moderate size (say, up to 10 000 unknowns) can be solved easily using either of the methods mentioned.

However, performance of these methods deteriorates, especially in three-dimension (3D), when finite element meshes are refined and thus the number n of unknowns in the system increases. The number of arithmetic operations for ICCG and ND grows as $n^{3/2}$ in 2D and as $n^{4/3}$ and n^2 , respectively, in 3D.

Multigrid methods are asymptotically much faster. Typically for these methods, the number of arithmetic operations per unknown is independent or almost independent of the size of the linear system being solved. This behavior is on a par with the fast Fourier transform (FFT) and the Greengard-Rokhlin multipole method.⁶ FFT, however, is applicable only to regular FE meshes (or a spatially uniform particle arrangement),¹⁶ while multigrid methods can be applied to

arbitrary tetrahedral meshes. Comparison with the multipole method is interesting and is planned for future work.

II. THE MAGNETOSTATIC MULTIPARTICLE PROBLEM

The magnetic scalar potential u of a system of magnetized particles satisfies the Poisson equation

$$\Delta u = \nabla \cdot \mathbf{M}, \quad (1)$$

where \mathbf{M} is the magnetization vector. For the purpose of computing the magnetostatic field, the magnetization of each of the particles is assumed to be known. Particles may have arbitrary orientation in space and, in principle, arbitrary shapes, although practical restrictions may be imposed by the capabilities of an FE mesh generator. The direction of magnetization may also be arbitrary.

In the weak (variational) form Eq. (1) can be written as

$$a(u, u') \equiv \langle \nabla u, \nabla u' \rangle = \langle \mathbf{M}, \nabla u' \rangle, \quad (2)$$

where the angle brackets denote an L_2 -type inner product of two vector functions in a given computational domain Ω , and u' is an arbitrary trial function from the appropriate Sobolev space. Different types of boundary conditions can be considered with Eqs. (1) or (2); for unbounded problems, the potential is assumed to be zero at infinity.

The FE method has already been successfully applied to multiparticle problems by Koehler, Yang, and Fredkin,^{1,2,8} but multigrid solvers have not been tried.

III. MULTILEVEL PRECONDITIONERS

The Bramble-Pasciak-Xu (BPX) multilevel preconditioners (MP)^{4,14,15,18,12} are among the least restrictive and the most efficient multigrid methods. The method is applicable to 2D and 3D magnetostatic problems (and to linear elliptic problems in general) and is suitable for highly irregular

FIG. 1. Mesh generation.

meshes and inhomogeneous materials. For the magnetostatic multiparticle problem on a mesh with n nodes, the asymptotic number of arithmetic operations for BPX-MP is¹⁵ $O(n)$. In addition, the BPX preconditioner is a double sum which can be computed in parallel.

A few levels of nested tetrahedral meshes are generated. In the simplest case of global refinement, each of the tetrahedral elements is subdivided into eight tetrahedra, thus obtaining the next level of triangulation. Associated with each level k ($k=1,2,\dots,m$) is a set of FE basis functions $\psi_i^{(k)}$ ($i=1,2,\dots,n_k$), where n_k is the number of nodes at level k , and a finite dimensional space P_k (of dimension n_k) spanned by these basis functions. Then $P_1 \subset P_2 \subset \dots \subset P_m$.

One of the simplest versions of the BPX preconditioner can be written as follows:^{14,4}

$$Br = \sum_{k=1}^m 4^{-k} \sum_{i=1}^{n_k} (r, \psi_i^{(k)}) \psi_i^{(k)}, \quad r \in P_m. \quad (3)$$

FIG. 2. Lines of equal scalar magnetic potential of one particle.

FIG. 3. Exact and multigrid solutions for one particle. (Tetrahedral mesh with over 600 000 elements.)

For the Poisson equation, the conjugate gradient method with the preconditioner B requires only $O(1)$ iterations to converge and $O(n)$ arithmetic operations. For inhomogeneous problems and/or highly irregular grids the preconditioner B in Eq. (3) needs to be modified, as proposed by Yserentant¹⁸ and further explained by Bornemann *et al.*³

$$Br = A_0^{-1}r + \sum_{k=1}^m \sum_{i=1}^{n_k} \frac{(r, \psi_i^{(k)})}{a(\psi_i^{(k)}, \psi_i^{(k)})} \psi_i^{(k)}, \quad (4)$$

where the operator A_0 corresponds to the FE representation of the bilinear form $a(u, u')$ on the coarsest mesh.

Adaptive refinement of the FE mesh may be needed to achieve the desirable accuracy of the numerical solution. Two main problems arise in connection with such refinement. First, if one of two elements having a common boundary is refined, the FE basis becomes nonconforming and the continuity of the solution must be explicitly imposed. Second, effective error estimates are needed in order to determine where the local refinement is needed.

Both of these problems can be solved simultaneously by using *hierarchical* FE bases,¹⁷ as proposed by Mitchell¹⁰ and R  de.¹¹ By setting the *hierarchical basis* value of an FE function at nonconforming ("slave") nodes to zero, the continuity of the function can be assured. At the same time, the hierarchical basis representation provides means of error estimation and control. The method is known as "fully adaptive multigrid" (FAM).^{10,11}

TABLE I. Number of iterations and solution time for the problem with one particle.

Level of refinement	Number of elements	Number of iterations ^a	Solution time (seconds) ^b
0	162	7	<1
1	1296	25	<1
2	10 368	40	<1
3	82 944	56	8
4	663 552	78	88

^aThe norm of the residual was reduced by a factor of 10–5.^bThe computations were performed on a personal computer with a Pentium II 300 MHz processor and 64 M RAM.

FIG. 4. The scalar magnetic potential for a model problem with three magnetized particles.

Our implementation of the multigrid algorithm is based on the BPX preconditioner transformed to the hierarchical basis. This approach combines the high convergence rate of BPX with the flexibility of local refinement provided by FAM. Representation of the magnetic scalar potential in the hierarchical basis ensures the continuity of the potential over nonconforming tetrahedral elements. In order to combine the hierarchical basis representation essential for FAM with BPX-MP, all vector variables and the BPX preconditioner are converted into the hierarchical basis.

IV. TESTING THE METHOD

Several test problems with magnetized particles were solved. To simplify mesh generation, the particles were considered to be parallelepipeds oriented parallel to the xy plane. The mesh initially consists of a set of prisms which are then subdivided into tetrahedra (Fig. 1).

The problem is solved on the finest mesh; the auxiliary coarser levels are needed only to construct the preconditioner. Since the domain properties are homogeneous (the Poisson equation is being solved), coarser meshes need not represent the exact geometry of the particles; rather, finer levels can be adaptively adjusted to the shape of the particles. (However, our current mesh generator exactly represents the geometry starting from the coarse mesh level.) Results for two of the model problems are presented below.

Problem 1. The main purpose of this test example was to compare the FE-multigrid solution with the analytical one. A cubic particle in free space is magnetized along the x axis. The analytical solution for the magnetic scalar potential is $u(r) = (1/4\pi) \int_S (\vec{M} \cdot d\vec{s}') / |r - r'|$. In FE analysis, the domain was bounded and homogeneous Dirichlet conditions were imposed on the boundary. The lines of equal magnetic potential are shown in Fig. 2. The magnetic potential distribution along the central line of the domain is shown in Fig. 3. The computational statistics are shown in Table I.

Problem 2. Three particles are magnetized along their axes (Fig. 4). Homogeneous Dirichlet boundary conditions are imposed on the external boundary. Computational statistics are shown in Table II.

TABLE II. Number of iterations and solution time for the problem with three particles.

Level of refinement	Number of elements	Number of iterations ^a	Solution time (seconds) ^b
0	1296	8	1
1	10 368	25	1
2	82 944	38	6
3	663 552	50	62

^aThe norm of the residual was reduced by a factor of 10^{-5} .

^bThe computations were performed on a personal computer with a Pentium II 300 MHz processor and 64 M RAM.

V. FUTURE WORK

The multigrid solver is to be incorporated into the overall micromagnetic simulation process. A straightforward approach would be to use the BPX preconditioner within the usual iterative procedure of minimizing the free energy. Whether or not energy minimization can be more fully integrated in the multigrid method remains an open question.

For open boundary problems, the modification of the multigrid method proposed by Hsiao and Zhang⁷ is promising. The asymptotic number of arithmetic operations remains the same as in a bounded problem. Comparison with the Greengard-Rokhlin fast multipole method, which has similar asymptotic characteristics, would be interesting.

It is anticipated that *a posteriori* error estimates will be implemented and used in the mesh refinement process.

VI. CONCLUSIONS

Magnetostatic fields in micromagnetic simulations are efficiently computed using multilevel preconditioners. A finite element problem with half a million elements can be solved in about a minute on a modern personal computer.

Modified scalar potential solution for three-dimensional magnetostatic problems

K. Sivasubramaniam,^{a)} S. Salon, and M. V. K. Chari

Department of Electric Power Engineering, Rensselaer Polytechnic Institute, Troy, New York 12180-3590

I. D. Mayergoyz

Department of Electrical Engineering, University of Maryland, Maryland 20742

A novel three-dimensional magnetostatic solution based on a modified scalar potential method has been developed. This method has significant advantages over the traditional total scalar, reduced scalar, or vector potential methods. The new method was successfully applied to a three-dimensional geometry of an iron core inductor and a permanent magnet motor. The results obtained are in close agreement with those obtained from traditional methods. © 1998 American Institute of Physics. [S0021-8979(98)38411-X]

I. INTRODUCTION

Solutions for two-dimensional magnetostatic field problems using a vector potential have been extensively reported in the literature.¹ However, there is a need for a computationally robust method particularly for three-dimensional field problems. Total scalar and reduced scalar^{2,3} potential solutions, and to a lesser extent three-dimensional vector potential⁴ solutions, or a combination of scalar and vector methods,⁵ have been presented by researchers. The scalar potential solutions do not suffer from the uniqueness problem that are encountered in the vector potential methods, although elaborate vector potential schemes of overcoming this difficulty have been described in the literature. The reduced scalar potential method allows current sources to be accurately represented and has, thus, found a wider application than the total scalar method because of the limitations of current sheet representation of sources and the need for branch cuts in the latter. However, even in the traditional reduced scalar potential method, the forcing function is evaluated over the entire solution domain and the zero divergence of the magnetic field due to current sources in free space is needlessly implemented resulting in numerical errors.

In this article, a three-dimensional modified scalar potential solution is described which minimizes numerical inaccuracies. In the new method, the forcing function is evaluated only in the iron region, and the zero divergence of the source magnetic field is eliminated from the computation.

II. THEORY

The fundamental theory behind the new method has been presented in an earlier paper,⁶ but is summarized here for completeness.

Since magnetic induction is divergence-free, the following equation may be written in terms of a reduced scalar potential formulation

$$\nabla \cdot [\mu(\bar{H}_c - \nabla\Phi)] = 0, \quad (1)$$

where \bar{H}_c is the magnetic field due to current sources (i.e., the rotational part of H), Φ is the scalar potential, μ is the permeability, and μ_0 is the free space permeability.

Since \bar{H}_c is divergence-free in free space,

$$\nabla \cdot (\mu_0 \bar{H}_c) = 0. \quad (2)$$

Subtracting Eq. (2) from eq. (1),

$$\nabla \cdot [(\mu - \mu_0)\bar{H}_c] - \nabla \cdot (\mu \nabla \Phi) = 0. \quad (3)$$

Applying the Galerkin weighted residual process to Eq. (3) using shape functions $\zeta_k (k=1,2,\dots,n)$,

$$\int_v \zeta_k \nabla \cdot [(\mu - \mu_0)\bar{H}_c] dv - \int_v \zeta_k \nabla \cdot (\mu \nabla \Phi) dv = 0. \quad (4)$$

This equation can be solved using the traditional finite element formulation for three-dimensional problems.

III. THREE-DIMENSIONAL APPLICATION TO AN IRON-CORE INDUCTOR

Figure 1 shows an octant of an iron core inductor excited by a current source (not shown in the figure) surrounding the central limb. The field H_c due to this current source is evaluated by Biot-Savart law separately. Equation (5) was solved

FIG. 1. Iron core inductor.

^{a)}Electronic mail: sivask@rpi.edu

FIG. 2. Flux density variation along X-X.

using a nonlinear finite element procedure with second-order isoparametric bricks. The field in the iron core was then computed as the sum of H_c and the negative gradient of the solution Φ . The flux density variation along X-X, obtained by this procedure is illustrated in Fig. 2.

IV. PERMANENT MAGNET FORMULATION

The flux density, \bar{B} , the magnetizing force \bar{H} and the intrinsic magnetization, \bar{M} , of a permanent magnet material are related by

$$\bar{B} = \mu \bar{H} + \mu_0 \bar{M}_0. \quad (5)$$

Since $\bar{H} = \bar{H}_c - \nabla \Phi$, Eq. (5) can be written as

$$\bar{B} = \mu (\bar{H}_c - \nabla \Phi) + \mu_0 \bar{M}_0. \quad (6)$$

Taking the divergence on both sides of Eq. (6), and setting it to zero yields

$$\nabla \cdot \bar{B} = 0 = \nabla \cdot \mu (\bar{H}_c - \nabla \Phi) + \nabla \cdot (\mu_0 \bar{M}_0). \quad (7)$$

Also,

$$\nabla \cdot (\mu_0 \bar{H}_c) = 0. \quad (8)$$

Substituting Eq. (8) into Eq. (7), as before, gives

$$\nabla \cdot [(\mu - \mu_0) \bar{H}_c] - \nabla \cdot (\mu \nabla \Phi) + \nabla \cdot (\mu_0 \bar{M}_0) = 0. \quad (9)$$

The weighted Galerkin formula yields

$$\begin{aligned} \int_v \zeta_k \nabla \cdot [(\mu - \mu_0) \bar{H}_c] dv - \int_v \zeta_k (\nabla \cdot \mu \nabla \Phi) dv \\ + \int_v \zeta_k \nabla \cdot (\mu_0 \bar{M}_0) dv = 0. \end{aligned} \quad (10)$$

Equation (10) is then solved by the three-dimensional finite element method in the traditional manner.

V. THREE-DIMENSIONAL PERMANENT MAGNET APPLICATIONS

Figure 3 shows a three-dimensional section of a six-pole permanent magnet motor. The rotor poles are of linear permanent magnet pieces, and the stator is of conventional design with one conductor per slot. The flux path is shown in

FIG. 3. Permanent magnet motor under no-load condition.

FIG. 4. Airgap flux density (no load).

FIG. 5. H_c —Flux due to current sources without effect of iron.

FIG. 6. Flux due to permanent magnet.

FIG. 7. Airgap flux density under load (directly demagnetizing case).

the figure by arrows representing the magnetic field intensity vectors. The flux density profile in the airgap is illustrated in Fig. 4 for the open circuit condition.

The short circuit condition with stator currents directly demagnetizing the rotor field is illustrated by the flux pattern in a cross section as shown in Figs. 5 and 6. The corresponding flux density variation in the airgap is given in Fig. 7.

The potentials obtained from these solutions are then used to compute engineering quantities like forces and inductances.

VI. CONCLUSIONS

An economical and efficient method for solving three-dimensional magnetostatic problems has been developed. The method has been applied to solve various three-dimensional problems including permanent magnet applications. The new method minimizes numerical inaccuracies by implementing the zero divergence of \vec{H}_c only in the iron parts. It also reduces the amount of computation necessary to solve the problem.

Numerical simulation of the magnetization structures in thin polycrystalline films with the random anisotropy and intergrain exchange

D. V. Berkov^{a)} and N. L. Gorn

INNOVENT e.V., Göschwitzer Str. 22, D-07745, Jena, Germany, and Institute of Physical High Technologies, Helmholtzweg 4, D-07743, Jena, Germany

We have developed a new algorithm which enables a fast and exact evaluation of the dipolar interaction field for lattice systems of magnetic moments when periodic boundary conditions should be applied. The method uses the combination of (i) the fast Fourier transformation technique for the dipolar field evaluation and (ii) the modified version of the Ewald method known from the calculations of the Coulomb lattice sums. The algorithm enabled us to perform large-scale numerical simulations of the remagnetization processes in polycrystalline thin magnetic films with the random single-grain anisotropy and the intergrain exchange. The well known ripple-like structures forming during the remagnetization process were observed. The dependence of the ripple correlation lengths and the hysteresis loop parameters on the intergrain exchange coupling and the film thickness was studied. © 1998 American Institute of Physics. [S0021-8979(98)23411-6]

I. INTRODUCTION

The most time-consuming part of any micromagnetic algorithm for the simulation of the equilibrium magnetization structures — including simulations of the quasistatic remagnetization processes — is the calculation of the dipolar interaction field (also called the demagnetizing or stray field) due to its long-range character.^{1–5} For finite samples or aperiodic magnetization structures with fixed boundary conditions, the application of the convolution theorem allows the usage of the fast Fourier transformation (FFT) technique with zero padding^{1,2} resulting in the operation count $\sim N \log N$ (where N is the total number of lattice sites or discretization cells), which is only slightly worse than for systems with the short-range interaction. However, in lattice systems with periodic boundary conditions direct application of the convolution theorem is not possible due to the already mentioned long-range character of the dipolar field. Various methods were suggested to overcome these difficulty,^{3–6} but all of them encounter serious problems: (i) cut-off of the dipolar interaction at some prescribed distance^{5,6} can be applied only to 2D models and introduces small but significant errors which can strongly influence the result especially in low external fields (see below); (ii) the so called hierarchical model⁴ suffers from the same drawback and, in addition, its implementation is quite complicated; (iii) direct solution of the Poisson equation for “magnetic charges,”^{3,7} enables to calculate the Fourier components of the dipolar field analytically, but the cut-off of the corresponding Fourier spectrum — even at arbitrary large frequency — introduces strong artificial oscillations into the calculated dipolar field, because Fourier components of, e.g., the stray field of the point dipole do not tend to zero for large wave vectors.

In this contribution we propose a method which combines advantages of the FFT technique for the computation of the long-range interaction field ($\sim N \log N$ operation

count) and of the Ewald method normally used for the calculation of the lattice sums for the Coulomb potential (the error by the field evaluation may be reduced to a vanishingly small value with only a minor — of order $\sim N$ — computational effort). Thus we obtain an algorithm which allows fast and exact evaluation of the dipolar interaction field in lattice systems with periodic boundary conditions.

II. METHOD FOR THE DIPOLAR FIELD EVALUATION

We are going to calculate the stray field created by the lattice of point-like dipoles. Following the basic idea of the Ewald method,^{8,9} we add and subtract at each lattice node $\mathbf{r}_{ij} \equiv (i, j)$ (which carries the dipole moment $\boldsymbol{\mu}_{ij}$) an artificial “Gaussian dipole” with total moment $-\boldsymbol{\mu}_{ij}$ and “magnetic charge” density given by

$$\rho_{ij}^G(\mathbf{r}) = -\frac{\delta(z)}{(2\pi)^{3/2}a^5}[(x-x_{ij})\mu_{ij}^x + (y-y_{ij})\mu_{ij}^y] \times \exp\left[-\frac{(\mathbf{r}-\mathbf{r}_{ij})^2}{2a^2}\right], \quad (1)$$

where the choice of the “dipole width” a will be discussed elsewhere.¹⁰ The charge density of the system can then be written as the sum $\rho(\mathbf{r}) = \rho_A(\mathbf{r}) + \rho_B(\mathbf{r})$, where the first part

$$\rho_A(\mathbf{r}) = \sum_{i,j=1}^{N_x, N_y} [\boldsymbol{\mu}_{ij} \cdot \nabla \delta(\mathbf{r}-\mathbf{r}_{ij})] + \sum_{i,j=1}^{N_x, N_y} \rho_{ij}^G(\mathbf{r}) \quad (2)$$

is the sum of the point dipoles [$\rho(\mathbf{r})$ of the initial system] and the contribution of the “negative” Gaussian dipoles (1). The second part

$$\rho_B(\mathbf{r}) = -\sum_{i,j=1}^{N_x, N_y} \rho_{ij}^G(\mathbf{r}) \quad (3)$$

represents the density of the “positive” Gaussian dipoles which should cancel the second sum in Eq. (2).

^{a)}Electronic mail: DBerkov@t-online.de

The advantage of this transformation is the following. For the first part, $\rho_A(\mathbf{r})$ the total moment attached to each lattice site is zero, because the total moment of the negative Gaussian dipole— μ_{ij} exactly compensates the moment of the corresponding point dipole of the initial system μ_{ij} . Hence the field created by magnetic charges of this first part $\rho_A(\mathbf{r})$ associated with each lattice site tends to zero faster than exponentially [to be more precise, as $\exp(-r^2/2a^2)$] and may be treated as a short-range interaction field, so it can be evaluated in $\sim N$ operations for the whole lattice. On the other hand, the second part $\rho_B(\mathbf{r})$ of the charge density is smooth, because it is given not by the point dipoles, but by the smooth Gaussian distribution at each lattice site. This means that the field created by $\rho_B(\mathbf{r})$ can be safely calculated using the solution of the corresponding Poisson equation and the FFT technique (see Introduction). Further details of the method will be reported elsewhere.¹⁰

III. NUMERICAL SIMULATIONS

We consider a thin magnetic film consisting of single-domain grains (crystallites) with saturation magnetization M_s forming a 2D hexagonal lattice. The magnetization \mathbf{M}_i inside each grain (cell) is assumed to be homogeneous, and hence is completely described by the unit vector $\mathbf{m}_i \equiv \mathbf{M}_i/M_s$. To calculate the equilibrium magnetization structure for the given external field we minimize a total system energy E taking into account, as usual, four energy contributions: (i) energy in the external field, (ii) energy due to the exchange between the neighboring crystallites, (iii) single-crystallite magnetic anisotropy energy and (iv) stray field energy:

$$\frac{E}{M_s^2 V_0} = - \sum_i \mathbf{m}_i \mathbf{h}_0 - \frac{C_{\text{exch}}}{2M_s^2 V_0 \langle ij \rangle} \sum_i \mathbf{m}_i \mathbf{m}_j - \frac{K}{M_s^2} \sum_i (\mathbf{m}_i \mathbf{n}_i)^2 - \frac{1}{2} \sum_i \mathbf{m}_i \mathbf{h}_i^{\text{dem}}, \quad (4)$$

where V_0 is the cell volume, reduced fields are defined as $\mathbf{h} \equiv \mathbf{H}/M_s$, K is the anisotropy constant. The constant C_{exch} which characterizes the strength of the exchange interaction can be evaluated from the exchange stiffness of the bulk material A , the hexagonal cell side b , the intergrain separation δ , the film thickness d , and the exchange weakening κ on the grain boundaries using the method described, e.g., in Ref. 11: $C_{\text{exch}} = \kappa \cdot A b d / \delta$; in the exchange term the sum is taken over the nearest neighbors $\langle ij \rangle$ only. Random space orientation of the crystallite anisotropy axes \mathbf{n}_i and periodic boundary conditions are assumed. To minimize the energy (4) we have used the simplest version of the relaxation method described in Ref. 2.

Numerical simulations which results are presented below were performed for a system with magnetic parameters corresponding to Co films ($A = 10^{-6}$ erg/cm, $M_s = 1400$ emu/cc, $K = 4 \times 10^6$ erg/cm³), film thickness $d = 10$ nm (when not stated otherwise), hexagonal cell side $b = 5$ nm, intergrain boundary thickness $\delta = 1$ nm. The magnetic structures shown in Fig. 1 and Fig. 4 are $N_x \times N_y = 64 \times 128$ cuts out of a lattice with 128×256 cells actually simulated (physical sys-

FIG. 1. Magnetization configuration (m_x -gray-scale maps) of the thin film near the coercivity for various exchange weakening degrees κ as indicated in the figure.

tem size $\approx 1.1 \times 1.9 \mu\text{m}$). All simulations were performed on the IBM Pentium PC 133 MHz. A typical run for a complete hysteresis loop (~ 40 values of the external field, $\sim 2 \times 10^4$ iterations totally) took about 10 hours.

IV. RESULTS AND DISCUSSION

Due to the limited paper length we present here in some detail only the dependence of the system behavior on the exchange coupling strength C_{exch} . Figure 1 demonstrates the magnetization structures at the coercivity point obtained by the simulation of the hysteresis loops for thin films with various values of the exchange weakening on the grain boundaries κ as indicated in the figure ($\kappa = 0$ means exchange decoupled grains, whereby, e.g., $\kappa = 0.1$ means that the exchange through a grain boundary is 10 times weaker than in the bulk). Initial direction of the external field was chosen parallel to the y direction in Fig. 1). The gray-scale map is used to present the x projection of the magnetization vectors $-1 < m_x < 1$, so Fig. 1 is supposed to simulate a standard Kerr-microscopy image. As expected, the average scale of the observed ripple structure (with stripes mostly perpendicular to the initial field direction) increases strongly with the exchange coupling at grain boundaries.

FIG. 2. Dependencies of the average ripple wavelength λ and the transverse correlation length L_t on the exchange weakening κ (statistical errors, where not shown, are smaller than the symbol size.)

FIG. 3. Dependencies of the reduced remanent magnetization j_R and the coercivity h_c on the exchange weakening κ .

To investigate this dependence qualitatively, we have studied the average ripple wavelength λ and the transverse correlation length of the m_x -component L_t (defined as the decay distance of the spatial m_x -correlation function in the direction perpendicular to the external field) as functions of κ . Corresponding dependencies are shown in Fig. 2. The growth of both correlation lengths with the exchange coupling is evidently faster than a linear one predicted by the linear and even by the nonlinear ripple theories (see, e.g., Ref. 12).

The exchange dependence of the most important hysteresis loop parameters — reduced remanent magnetization $j_R = M_z(H=0)/M_s$ and reduced coercivity $h_c = H_c/M_s$ — is presented in Fig. 3. First of all, we point out that the remanence j_R for low exchange coupling differs significantly from that obtained using the cut-off method^{5,6} and the hierarchical model.⁴ This discrepancy is probably due to the small errors introduced by these both latter methods. Indeed, performing special test runs we have found that adding random errors with the relative magnitude ~ 0.01 – 0.02 to the exact stray field values evaluated by our method leads to a significant increase of the remanence especially in the case of small exchange coupling where the dipolar interaction is of a major importance. The second difference with the known results^{4–6} is the stronger decrease of the coercivity for large values of the exchange coupling obtained in our simu-

FIG. 4. Remanent magnetization states shown as m_x -gray-scale maps for various film thicknesses d as indicated in the figure.

lations which may be due to the much larger system size used by us. Namely, large correlation lengths occurring for strong exchange couplings (see Fig. 2) may lead to substantial finite-size effects for smaller system sizes.

We have also studied the dependence of the parameters discussed above on the film thickness d . Remanent magnetization states obtained for various film thicknesses are shown in Fig. 4. Here we would like only to point out that for a very thin film (where the intergrain interaction is almost negligible) the almost random magnetization pattern is formed (see image for $d=1$ nm) whereby for the thicker films the ripple structure became more and more pronounced. Detailed results of these studies, discussion of their relation to the available experimental data and of the applicability of our method to numerical simulations by finite temperatures will be presented elsewhere.¹⁰

Finite element analysis of the influence of a fatigue crack on magnetic properties of steel

Y. Shi and D. C. Jiles

Center for Nondestructive Evaluation, Iowa State University, Ames, Iowa 50011

Fatigue can affect the magnetic properties of materials due to microstructural changes. Previous investigations have shown that several structure sensitive magnetic properties, such as coercivity H_c and remanence B_r , changed systematically as a result of fatigue. When approaching failure the accumulated changes in microstructure resulted in the occurrence of fatigue cracks and the magnetic properties showed dramatic changes which mainly resulted from the geometrical changes in samples due to the cracks. It was found that the remanence B_r followed the changes in stress, while the coercivity H_c sometimes showed different trends. In this article the influence of the size and the position of a fatigue crack on magnetic field and magnetic induction were studied using finite element modeling. Models were constructed to simulate the geometry of the test sample and sensor. It was found that, for a given coil current in the exciting coil, the magnetic induction was mainly determined by the geometry of the crack, while the magnetic field was influenced by both the size and the position of the crack. © 1998 American Institute of Physics. [S0021-8979(98)50711-6]

I. INTRODUCTION

In recent years there has been increased interest in correlating magnetic properties of ferromagnetic materials with their mechanical properties.^{1,2} The evolution of the magnetic properties during fatigue is of particular interest because of the relation between the fatigue and magnetic properties of materials.³⁻⁵ It has been shown that the measured magnetic properties change systematically throughout the fatigue lifetime. When approaching failure, the cumulative stress results in the occurrence of cracks, which normally start from the outer surface. After cracks appeared there was little overall change in the microstructure of the materials because most stresses then concentrated at the tip of the crack and the main change subsequently was the growth of the crack. During this period, the corresponding changes of magnetic properties mainly resulted from geometrical changes in the samples because of crack growth. It was found during this period that the remanence B_r still depended primarily on the crack geometry although the coercivity H_c sometimes showed different trends.

To explain the above observations magnetic finite element modeling (FEM) work was conducted to establish the relation between the fatigue crack geometry and the surrounding magnetic field distribution. Finite element analysis techniques, although yielding only approximate solutions to the classical partial differential equations of the electromagnetic field, are particularly attractive for the study of field distribution within magnetic structures having complex boundary configurations. This property makes the method very suitable for the analysis of the interaction between the magnetic field and defects within materials, and thus it has been applied to magnetic leakage field inspection⁶⁻⁸ and creep damage detection.⁹ In this article, it is shown that the method can be extended to fatigue analysis.

II. FINITE ELEMENT MODELING

The general geometry of the FEM solid model is shown in Fig. 1. The shape of the fatigue sample on which experimental measurements were made was a cylindrical rod which was subjected to a uniaxial cyclic stress. An inductive magnetic sensor consisting of a search coil wound on a magnetic C core was used to measure the magnetic properties of the sample during the fatigue lifetime. The magnetic field was measured using a Hall probe which was located at the center of the C core and on the surface of the sample. Magnetic induction was measured using a detection coil which was wound on the core of the sensor. To simplify the modeling two-dimensional representations were constructed to simulate the geometry of the sample and sensor. The magnetic field values were calculated at the location of the Hall probe and the magnetic induction values were calculated from the throughout the volume of the detection coil.

The amplitude of the excitation current was small enough that the sensor operated in the low field hysteresis

FIG. 1. Geometry for the finite element model calculation.

FIG. 2. Calculated magnetic field H vs crack depth in the position with the crack on the side of the specimen facing the C core and positioned at the center of the sensor.

FIG. 3. Calculated magnetic field H vs crack depth in the position with the crack on the side of the specimen facing the C core and positioned away from the center of the sensor.

region which can be considered as approximately linear. So the magnetic properties of the sensor material were assumed linear to simplify the problem. However, nonlinear B - H data, which were measured experimentally, were used for the sample material, because different regions would have different magnetic states during fatigue after the crack generated.

The vector potential formulation was employed to conduct calculations.¹⁰ With this method it is possible to calculate the flux passing through a predefined line contour. At first calculations were conducted to determine the magnetic field distribution of the whole system for different crack sizes and positions under a fixed excitation current. Then the magnetic field value at the Hall probe (location 1 in Fig. 1) and the magnetic induction at the detection coil (location 2 in Fig. 2) were calculated.

III. RESULTS AND DISCUSSION

The magnetic field in the specimen was influenced by both the crack size and its position as shown in Figs. 2–4. This is because the magnetic field distribution in the space between the sample and the C core was mainly determined by two factors: the leakage field of the corners and tips of the crack and the demagnetizing effect generated by the crack surfaces. The leakage field increased as the crack grew, which resulted in a larger field amplitude. However growth of the crack also increased its surface area which led to an increase in the demagnetizing effect and hence reduction of the magnetic field. When the crack was located below the C core at the center of the sample, the leakage field dominated. The resultant field increased with the crack size as shown in Fig. 2. When the crack did not occur at the midpoint, the demagnetizing effect of crack surfaces altered the magnetic field. Therefore, as the crack was initiated, the magnetic field at first decreased because of the demagnetizing field from the crack surface. Later it increased because of the leakage field introduced by the corners of the crack as shown in Fig. 3. As the distance between the probe and the crack increased, the

influence of the demagnetizing effect on the resultant amplitude of the magnetic field became greater, and the influence of the leakage field became less.

A similar explanation can be applied to the case when the crack is on the side of the specimen opposite from the C core. The only difference is that the leakage field generated by the tip of the crack dominated in most cases. The demagnetizing effect hardly influenced the magnetic field in the immediate vicinity of the crack. Only when the crack was farther away from the center of the sample did the influence of demagnetizing effect on the magnetic field become apparent as shown in Fig. 4.

Compared with the magnetic field H , the resultant magnetic induction B exhibited much smaller changes with the crack geometry as shown in Fig. 5. This result can be explained because the detection coil measured the flux change in the sensor, which was distant from the crack region. Therefore, the measured magnetic induction was an average

FIG. 4. Calculated magnetic field H vs crack depth in the position with the crack on the opposite side of the specimen from the C core and away from the center of the sensor.

FIG. 5. Calculated magnetic induction B vs crack depth in the position with the crack on the opposite side of the specimen from the C core and away from the center of the sensor.

which was much less influenced by the two effects than was the highly localized magnetic field. The main factor influencing the resultant magnetic induction was the size of the air gap which was introduced by the crack into the magnetic circuit. This increased the magnetic reluctance around the flux path and resulted in a decrease in magnetic induction with crack size under the same magnetomotive force as shown in Figs. 5 and 6.

IV. CONCLUSIONS

The interactions of the magnetic field and the fatigue crack were modeled using finite element techniques. It was found that the detected magnetic field was determined principally by two factors: the leakage field of the corners and tips of the crack and the demagnetizing effect of the crack surfaces. These two factors had opposite effects on the detected magnetic field amplitudes. On the other hand, the calculated magnetic induction appeared to be only determined by the crack geometry.

FIG. 6. Calculated magnetic field H and magnetic induction B vs crack width and depth with the crack on the side of the specimen facing the C core and located at the center of the sensor.

Magnetohydrodynamic calculation for free surfaces

Keisuke Fujisaki and Takatsugu Ueyama

Process Research Tech Labs. Nippon Steel Corp., 20-1 Shintomi, Futtsu-city, Chiba 293-8511, Japan

A magnetohydrodynamic calculation for free surface is used in the design and evaluation of a cold-crucible or initial solidification such as stirring phenomena commonly found in the metal processing industry. A direct calculation of both the electromagnetic field and the fluid dynamics field for the surface of a molten metal that changes with time requires significant computing times, especially for three-dimensional models. An approximate calculation method, the shadow method, is one which uses a fixed mesh. Results obtained by the shadow method show that the shape of molten metal does not collapse under gravity as observed experimentally. © 1998 American Institute of Physics. [S0021-8979(98)33011-X]

I. INTRODUCTION

A magnetohydrodynamic calculation for free surface is used in the design and evaluation of cold-crucible or initial solidification such as stirring phenomena commonly found in the metal processing industry.¹⁻³ The magnetohydrodynamic calculation is necessary for an electromagnetic field calculation based on Maxwell equations and a flow dynamics calculation based on the Navier–Stokes equations. A direct calculation method that allows for the surface of the molten metal to change with time requires significant computing times, especially for three-dimensional models. Hence an approximate scheme of calculation is desirable.

In a free surface calculation, the shape of molten metal changes with time and the numerical solutions are iterated to within a certain error. Since the shape of the molten metal changes, a moving mesh calculation method is used.⁴ However, using a moving mesh requires extra calculations needed to solve for the mesh positions. Moreover, the influence of the flow dynamics on the free surface shape is ignored. Only the balance of electromagnetic and gravitational forces is considered. Here, we propose a shadow method on a fixed mesh.

II. CALCULATION METHOD

A. Direct method

Figure 1 shows the results of a magnetohydrodynamic calculation using the direct method. Through an electromagnetic analysis, the electromagnetic force is calculated, and the fluid dynamics is analyzed using the condition that the electromagnetic force is the driving force for the fluid dynamics. During the fluid dynamic analysis, the velocity and the mesh shape are calculated, and the electromagnetic forces are analyzed using the condition that the velocity makes the electromotive force, and the mesh shape provides the new boundary condition.

Here, the eddy current field and the quasistationary field are assumed in the electromagnetic analysis.⁵ Turbulent flow in the fluid dynamic analysis is assumed, because the Reynolds number is as large as 10^5 – 10^6 . The direct method has been used for a two-dimensional model using a static condition.^{6,7} However, calculations of the electromagnetic

fields and fluid dynamics in the case of a three-dimensional model or one with transient dynamics requires a lot of computation. Hence an approximate shadow method is described and tested in this article.

B. Shadow method

Figure 2 shows the results of a magnetohydrodynamic calculation using the shadow method proposed here. The shadow method is used to model the electromagnetic fields in a flow dynamic calculation. The problem to be solved is how to calculate the new electromagnetic forces when the shape of molten metal changes as a result of the old electromagnetic forces. Usually, the new electromagnetic forces are different from the old electromagnetic forces whenever the shape of molten metal changes. In the shadow method, it is assumed that the electromagnetic field is the same when the clearance between the coil and the molten metal is the same.

In the shadow method, we consider one line in the molten metal to be solved. The line could be selected to be along a direction in which the molten metal shape changes. Along this line, we can make any point of the molten metal which does not change shape corresponds to a certain point of the molten metal which changes under the influence of the old electromagnetic force distribution. Then the new electromagnetic force in the molten metal can be obtained from this one to one correspondence.

The flow dynamics calculation for a free surface uses a fixed mesh. The mesh in free surface is expressed as the occupation rate of the molten metal. The curve of the free surface is made smooth on the mesh, where the pressure is equal.⁸

FIG. 1. Magnetohydrodynamic calculation by direct method.

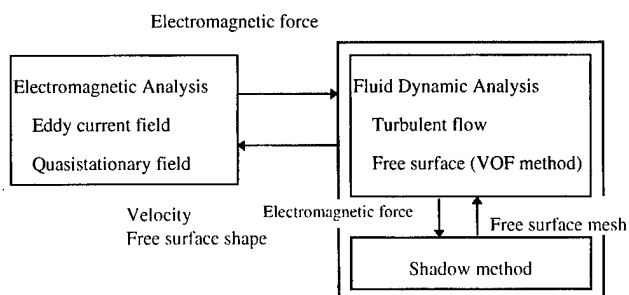

FIG. 2. Magnetohydrodynamic calculation by shadow method.

The shadow method is based on a modeling method called MORDY, which stands for moving reference frame model for multibody.⁹ The MORDY approach is used in dynamic calculations such as in electromagnetic levitated vehicles.¹⁰

III. CALCULATION RESULTS

A. Calculation method

Figure 3 shows the calculation model here. To test the validity of the shadow method, we use a cylindrical two-dimensional non-static model. The z direction is the line that is selected. Along this line, the electromagnetic force is shadowed from the old molten metal to the new molten metal. This model is used in the initial solidification in continuous casting.⁶

The electromagnetic forces are calculated using a general solver of electromagnetic fields called FLEDY.¹¹ The

FIG. 3. Calculation model (cylindrical 2D model).

electromagnetic force is applied to the molten metal for the first 0.1 s. The calculation time of fluid dynamics is 2.0 s.

B. Calculation results

Figure 4 shows the calculated results without the shadow method. For $z > 0.0557$ m, no electromagnetic forces are applied to the molten metal as shown in (2-1) of Fig. 4 (the

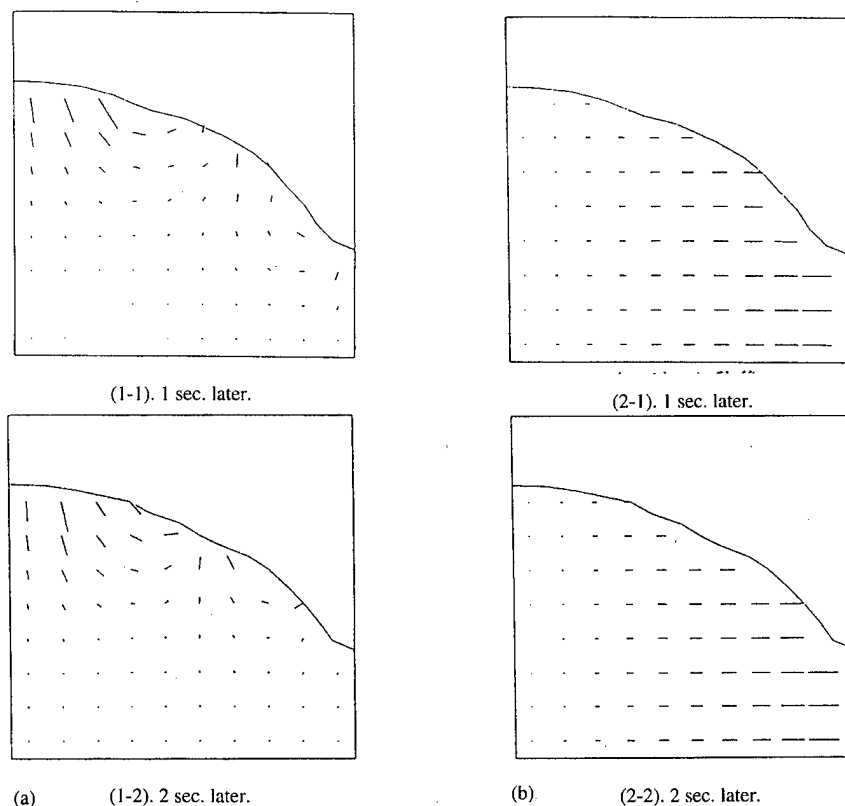

FIG. 4. Calculation results by no shadow method. (a) Velocity distribution. (b) Electromagnetic force distribution.

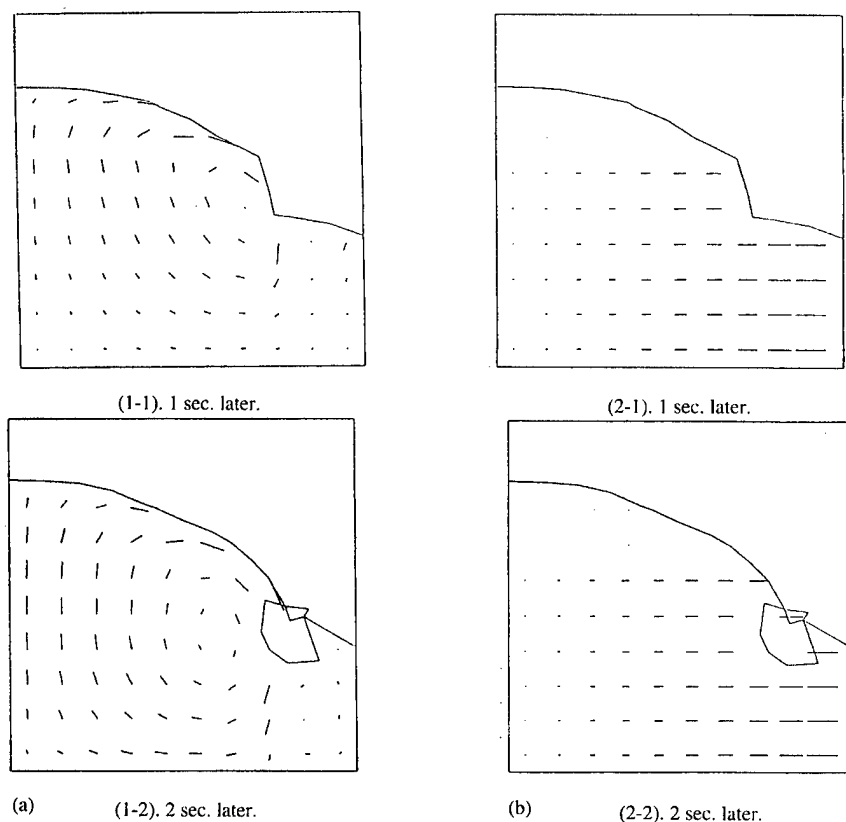

FIG. 5. Calculation results by shadow method. (a) Velocity distribution. (b) Electromagnetic force distribution.

electromagnetic force distribution after 1.0 s). The molten metal near the center line rises, and then falls down because there is no electromagnetic force to support it, as shown in (1-2) of Fig. 4 (the velocity after 2.0 s). This contradicts experimental observations during initial solidification,⁶ in which collapse of the metal does not occur. The electromagnetic force only supports the molten metal in the first few seconds.

On the other hand, Fig. 5 shows the calculated results with the shadow method. In contrast to the direct calculation, for $z > 0.0557$ m electromagnetic forces are applied to the molten metal as shown in the corresponding panel (2-1) of Fig. 5. The molten metal near the center line also rises up. However, the molten metal does not fall down because the electromagnetic forces support the molten metal, as shown in (1-2) of Fig. 5.

IV. CONCLUSION

A shadow method is proposed here as the modeling method for free surface magnetohydrodynamic calculations.

The results obtained by the shadow method show that the shape of molten metal does not collapse under gravity in accordance with experimental observations.

Differential Preisach model for the description of dynamic magnetization processes

P. Andrei, Al. Stancu,^{a)} and O. Caltun

"Al. I. Cuza" University, Faculty of Physics, Iasi, 6600, Romania

A differential dynamic Preisach model developed by us and introduced as an idea suggested by Bertotti is generalized. The starting point of this model is that the instantaneous excess field due to the moving and dynamic processes can be approximated as a function of M and its variation rate dM/dt : $F(M, dM/dt)$. Thus, we determine a differential equation for the magnetic susceptibility. The model's parameters are found by an original identification method. As an application we simulate a simple electrical circuit and compare the results with the experimental data. A very good agreement between the measured and simulated data is observed. © 1998 American Institute of Physics. [S0021-8979(98)33111-4]

I. INTRODUCTION

Generally, the actual phenomenological models for the magnetic hysteresis¹⁻⁴ are given by a differential equation for the magnetization (or induction) and they try to fit theoretical curves to experimental data. Usually, this differential equation (the model equation) is of the first order and one can determine the susceptibility χ (or permeability) as a function of the magnetization M , of the applied field H , and of their variation rate (\dot{M} and \dot{H}). If χ depends on all these variables then the model is called a dynamic model and if χ is only a function of M and H , the model is a static one. Integrating $\chi(H, M, \dot{H}, \dot{M})$ one obtains the magnetization M as a function of time. There have also been a few attempts^{3,4} to present some dynamic Preisach models in a mathematical form but none of them gives a differential equation. This makes it very difficult to use the Preisach model in many applications where the dynamic effects must be taken into account such as: simulation of electrical circuits that contain a coil with a nonlinear core or prediction of some magnetization processes where H is given by a differential equation.

In this article we have generalized a dynamic Preisach model (DPM) recently developed by us.⁵ It is known⁶ that the dynamic effects in a magnetic core (such as the effects produced by eddy currents) can be taken into account by supposing that the effective magnetic field is the sum between the applied field and an excess instantaneous field which depends on the variation rate of M . To consider a classical moving term depending on M as well, we suppose that the effective field is the sum of the applied field, H , and a general moving term, $F(M, \dot{M})$, depending on M and \dot{M} :

$$H_{\text{eff}} = H + F(M, \dot{M}). \quad (1)$$

Due to the symmetry of the major loop the general moving function F must satisfy the condition $F(M, \dot{M}) = -F(-M, -\dot{M})$.

II. DYNAMIC PREISACH MODEL

In order to find an analytical expression for the magnetic susceptibility in DPM we will employ a method developed

by us previously.⁵ We consider the generalized moving Preisach model with the effective field given by (1). The Preisach distribution function is assumed to be the product of a Gaussian distribution in the interaction field and a log-normal distribution in the coercive field:

$$P(H_\alpha, H_\beta) = P_0 P_i \left(\frac{H_\alpha + H_\beta}{\sqrt{2}} \right) P_c \left(\frac{H_\alpha - H_\beta}{\sqrt{2}} \right), \quad (2)$$

with (P_0 is a normalization factor):

$$P_0 = \frac{SM_s H_0}{2\pi H_{\sigma i} H_{\sigma c}}, \quad P_i(h) = \exp\left(-\frac{h^2}{2H_{\sigma i}^2}\right), \quad (3)$$

$$P_c(h) = \frac{1}{h} \exp\left[-\frac{\ln^2(h/H_0)}{2(H_{\sigma c}/H_0)^2}\right],$$

where $H_{\sigma i}$ and $H_{\sigma c}$ are distribution standard deviations, H_0 is the center of the distribution after coercivities and M_s is the saturation value of the magnetization. The factor S represents the weight of the irreversible part in the total magnetization of the sample. The reversible component of the model is given by:

$$R(H_\alpha) = \frac{(1-S)M_s}{2H_{\sigma r}} \exp\left(-\frac{|H_\alpha|}{H_{\sigma r}}\right), \quad (4)$$

where $H_{\sigma r}$ is a fit parameter.

In order to find the susceptibility in DPM, we differentiate the total magnetization of the generalized moving Preisach model with respect to the magnetic field. Using the same method presented earlier⁵ one finds the differential equation:

$$\frac{d\chi}{dt} = \frac{1}{F'_{\partial M}(M, \dot{M})} + \frac{[F'_M(M, \dot{M})\dot{H} - F'_{\partial M}(M, \dot{M})\ddot{H}](I+J) - \dot{H}}{(I+J)F'_{\partial M}(M, \dot{M})\dot{H}} \chi, \quad (5)$$

where we have introduced the notations:

^{a)}Electronic mail: alstancu@uaic.ro

$$I = \begin{cases} 2 \frac{\partial E(H_{N \text{ eff}}, H_{\text{eff}})}{\partial H_{\text{eff}}} = 2 \int_H^{H_{N \text{ eff}}} P(h, H_{\text{eff}}) dh, & \text{if } H \text{ is increasing;} \\ 2 \frac{\partial E(H_{\text{eff}}, H_{N \text{ eff}})}{\partial H_{\text{eff}}} = 2 \int_{H_{N \text{ eff}}}^H P(H_{\text{eff}}, h) dh, & \text{if } H \text{ is decreasing;} \end{cases} \quad (6)$$

(H_{eff} is the value of the effective field, $H_{N \text{ eff}}$ is the last extreme value of the effective field in the Preisach plane), and

$$J = 2R(H_{\text{eff}}). \quad (7)$$

The functions $F'_M(M, \dot{M})$ and $F'_{\dot{M}}(M, \dot{M})$ represent the partial derivatives of F with respect to M and \dot{M} , respectively. The function E is the Everett integral defined as:

$$E(H_x, H_y) = \int_{-H_0}^{-H_0 + (H_x - H_y)/2} \left[\operatorname{erf}\left(\frac{H_x - H_0 - h}{H_{oi}}\right) - \operatorname{erf}\left(\frac{H_y + H_0 + h}{H_{oi}}\right) \right] P_c(h + H_0) dh, \quad (8)$$

where erf is the error function.⁷ The functions I and J represent the irreversible and the reversible part of the susceptibility in the generalized Preisach model, respectively.

The choice of the function F is a quite intricate problem. Bertotti⁶ has shown that the average excess field in a half hysteresis loop depends on the average magnetization rate as $H_{\text{exc}} = -\beta \operatorname{sgn}(\dot{M})(\sqrt{1 + \gamma|\dot{M}|} - 1)$, where β and γ are two parameters that depend on the material. In this article we suppose that at each point of the hysteresis loop the instantaneous excess field is given by the same equation where \dot{M} is the instantaneous magnetization rate. Thus, the generalized moving function is:

$$F(M, \dot{M}) = \alpha M - \beta \operatorname{sgn}(\dot{M})(\sqrt{1 + \gamma|\dot{M}|} - 1), \quad (9)$$

where α is the moving parameter.³ The existence of the excess magnetic field H_{exc} that adds to the applied magnetic field implies an important variation of the coercive field of the major hysteresis loop with the frequency of the applied field. Thus one can determine the parameters β and γ by measuring the coercive field for different \dot{M} .

III. IDENTIFICATION METHOD

There are some identification methods for the Preisach distribution but all of them are quite intricate and need many experimental data (e.g., Mayergoyz³). In this section we propose a robust identification method for the Preisach distribution's parameters (M_s , H_{oc} , H_{oi} , H_{oc} , H_0 , and S) and for the moving parameter α from the experimental major hysteresis loop and the experimental remanent major loop, respectively.

In order to determine the distribution's parameters we have used the following method. First, one determines from the static hysteresis loop: the coercive field H_c , the remanent magnetization M_r , the magnetization at the upper branch of the loop for the coercive field M_c , and the energy lost per cycle (the surface of the loop) w , the closure field (the field where the upper branch of the major loop touches the lower

branch) H_{cl} , the saturation field H_s and the susceptibility at H_{cl} and H_s [$\chi(H_{cl})$ and $\chi(H_s)$, respectively]. Then, one determines the parameters M_s (as the saturation value of the major loop) and H_{oc} from the equation:

$$H_{\text{oc}} = \frac{H_s - H_{cl}}{\chi(H_{cl}) - \chi(H_s)}, \quad (10)$$

(the susceptibility for field greater than H_{cl} is given by the reversible part of the susceptibility). Finally, one follows the iteration:

- (1) One starts from two "first guess" values of the parameters H_0 and H_{oc} (in our simulation we have always started from $H_0 = H_c$ and $H_{\text{oc}} = H_c$).
- (2) One determines S from the condition that the surface of the major loop is w :

$$S = \frac{\sqrt{\pi} w H_{\text{oc}}}{4 M_s H_0} \left[\int_0^\infty P_c(\sqrt{2}h) h dh \right]^{-1}. \quad (11)$$

- (3) The H_{oi} parameter is determined from the remanent magnetization M_r by solving the next transcendental equation:

$$M_r = \frac{S M_s H_0}{\sqrt{\pi} H_{\text{oc}}} \int_0^\infty P_c(\sqrt{2}h) \operatorname{erf}\left(\frac{h}{H_{oi}}\right) dh. \quad (12)$$

- (4) The H_0 parameter is determined from the coercive field H_c by solving the transcendental equation:

$$\frac{S M_s H_0}{\sqrt{\pi} H_{\text{oc}}} \int_0^\infty P_c(\sqrt{2}h) \operatorname{erf}\left(\frac{H_c - h}{H_{oi}}\right) dh + 2 \int_0^{H_c} R(h) dh = 0. \quad (13)$$

- (5) One repeats steps 2, 3 and 4 until the convergence is attained (in our simulations we imposed that the actual values of the S , H_{oi} , and H_0 differ from the old ones with a relative error of 10^{-3}).
- (6) One determines the actual value of M_c from the upper branch of the major loop (we denote this value by M'_c):

$$M'_c = \frac{S M_s H_0}{\sqrt{\pi} H_{\text{oc}}} \int_0^\infty P_c(\sqrt{2}h) \operatorname{erf}\left(\frac{H_c + h}{H_{oi}}\right) dh + 2 \int_0^{H_c} R(h) dh. \quad (14)$$

- (7) If $|M'_c - M_c| < \epsilon$ (where ϵ is a small parameter that ensures the convergence; we considered $\epsilon = 10^{-3} M_s$) then one stops the iteration; else one pass to the next step.
- (8) One determines the new value of H_{oc} by adding to the old value of H_{oc} the term $\xi(M'_c - M_c)$, where ξ is an appropriate relaxation factor. This constant has to be sufficiently great in order to increase the convergence rate of the algorithm but not so large that it causes the algorithm to diverge (in our simulations we considered $\xi = 1/M_s$). Then one passes to step 2 and one repeats the algorithm.

In order to determine the moving parameter α we used the following algorithm. One starts with a "first guess" value for the moving parameter α (in our simulations we have started with $\alpha = 0$) and transforms the experimental major loop in the operational plane (the operational plane is the plane $(M, H + \alpha M)$). One determines the distribution's parameters using the method presented above and then the new value of the moving parameter by adding to the old value, the quantity:⁸

FIG. 1. Static hysteresis loops: experimental (points) and simulated (continuous line).

$$\Delta\alpha = \frac{H_c'(\text{rem}) - H_c(\text{rem})}{M(H_c'(\text{rem}))}, \quad (15)$$

where $H_c(\text{rem})$ and $H_c'(\text{rem})$ are the coercive fields of the experimental and the simulated remanent major hysteresis loops, respectively, and $M(H_c'(\text{rem}))$ is the simulated magnetization corresponding to $H = H_c'(\text{rem})$. One continues the iteration until $\Delta\alpha$ is negligible.

IV. RESULTS AND DISCUSSIONS

The experimental setup consists of a RL circuit in series with an ac generator. The inductance L is a MnZn soft magnetic torus (A-41) having the inner radius $r_1 = 23$ mm, the outer radius $r_2 = 35$ mm, and the high $h = 20$ mm. The experimental magnetic hysteresis loop is determined using a digital storage oscilloscope.⁹

Using the identification method presented above we have obtained the next set of parameters: $M_s = 3.2 \times 10^{-5}$ A/m, $S = 0.23$, $H_{\sigma 1} = 27.5$ A/m, $H_{\sigma 2} = 67.1$ A/m, $H_{\sigma 3} = 111.0$ A/m, $H_0 = 74.4$ A/m, and $\alpha = 1.13 \times 10^{-4}$. The experimental and the simulated static hysteresis loops are shown in Fig. 1. In Fig. 2 is shown the dc demagnetization (which is used in the identification of α) and the isothermal remanent magnetization curves. The identification method ensures that the coercive field H_c , the magnetizations M_r and M_c and the losses (the area) in one major hysteresis loop are the same as the experimental ones. The dynamic parameters β and γ are

FIG. 2. Experimental (points) and simulated (continuous line) remanent magnetization curves: IRM for positive fields and DCD for negative fields.

FIG. 3. Dynamic hysteresis loops for $\nu = 1$ kHz: experimental (points) and simulated (continuous line).

calculated from least-squares criteria applied to the simulated and experimental wave form magnetization in the dynamic loop. We present in Fig. 3 the dynamic hysteresis loop, obtained for the frequency of the applied field $\nu = 1$ kHz. One observes a substantial increase of the coercive field (approximately five times) that is characteristic to the soft ferrites.

V. CONCLUSIONS

Various magnetization processes were simulated with a differential Preisach model. The dynamic processes were taken into account using a simple phenomenological assumption: the effective field in the Preisach plane is the sum of the applied field and a generalized moving field depending on the instantaneous magnetization and its variation rate. The same method can be applied to all the phenomenological models of hysteresis (e.g., the Jiles–Atherton model and Hodgdon model). We have deduced a differential equation for the magnetic susceptibility, analogous to that previously presented.

In order to determine the model's parameters we have developed a robust identification method that needs the experimental major hysteresis loop (for the distribution parameters) and the experimental dc demagnetization curve (for the moving parameter). A very good agreement is observed between the simulated and experimental curves.

Influence of the permanent magnet overhang on the performance of the brushless dc motor

J. P. Wang and D. K. Lieu

University of California, Berkeley, California 94720

W. L. Lorimer and A. Hartman

Quantum Corporation, Milpitas, California 95035

Axial overhang of the permanent magnets has been used to enhance the performance of radial flux brushless dc motors, but its precise contribution to performance is not well known. This article aims at the investigation of the overhang effects by finite element and lumped parameter modeling. An empirical formula which allows two-dimensional analysis to account for overhang effects is proposed. A three-dimensional equivalent magnetic circuit model is developed and its ability to accurately predict overhang effects is assessed. Results of finite element and lumped parameter models are compared and a design methodology is forwarded. © 1998 American Institute of Physics. [S0021-8979(98)46911-1]

I. INTRODUCTION

High performance and low power brushless dc motors continue to be the trend in the hard disk drive (HDD) industry. Axial overhang of the permanent magnets has been used to enhance the performance of radial flux brushless dc motors, but its precise contribution to performance is not well known. Besides adding cost, there are three other reasons why it is not wise to use overhang without knowing its proper length. First, not all the extra magnetic flux produced by magnet overhang produces useful torque. Second, the originally preferred trapezoidal back EMF shape will be distorted if the flux increment is not uniform at all rotor positions. Third, magnet overhang is not effective in improving performance unless the stator has been sized to accommodate the additional flux. The purpose of this paper is to investigate the overhang effects by three-dimensional (3D) finite element (FEM) and lumped parameter modeling (LPM). The former is favored for its high accuracy in handling highly nonlinear magnetic field in electrical machines. The latter is popular for its fair accuracy but quick repetition of computation.

To account for magnet overhang and end leakage effects, which can be significant in low-profile motors, a 3D model is required. The data storage space and CPU time required for a 3D finite element model, however, may be prohibitive.

Lumped parameter modeling, an alternative to FEM, has a good capability in predicting magnetic flux and back EMF in 2D problems.¹ The model is extended to 3D by adding permeances representing extra flux and leakage paths to the original magnetic circuit built for 2D problem.

A typical 8-pole 12-slot spindle motor used in the HDD is used in this analysis. To illustrate three-dimensional effects, magnetic flux and back EMF are computed for different overhang lengths as a function of rotor position. Different permanent magnet strength (remanence) is applied to achieve different saturation levels. Overhang effects predicted by FEM and LPM are compared, and recommenda-

tions for accurately predicting optimum magnet overhang without a full 3D finite element analysis are forwarded.

II. 3D MODEL DESCRIPTION

A. Finite element model

The top view of a typical 8-pole 12-slot spindle dc spindle motor and a description of the finite element mesh is shown in Fig. 1 (and Table I, respectively). The aspect ratio (airgap diameter divided by stator height) for this motor is a moderate 2.5, but ratios as high as 10 are common in HDD motors. Permanent magnets are modeled with radial magnetization, materials are assumed isotropic and hysteresis effects are ignored. The size of analyzed domain can be reduced to one octant by taking advantage of the symmetry and imposing the proper boundary conditions. The angular size of the elements in the airgap are chosen to be the same as that of rotor step angle in order to maintain mesh uniformity and in turn improve accuracy. In selecting axial mesh density, models of increasing coarseness are solved. The coarsest mesh to produce the converged (fine mesh) solution is chosen for speed considerations. Solution time for a single rotor position ranges from 2 hours to 8 hours in the nonlinear cases.

FIG. 2. 3D lumped parameter model permeances.

FIG. 3. The effect of the size of magnet deadzone on the flux increment, 15% overhang.

FIG. 4. The effect of the size of slot opening on the flux increment, 15% overhang.

FIG. 5. The effect of the saturation level and overhang on the flux increment, $B_r=0.71$ in nonlinear cases.

FIG. 6. Flux increments for motors with various aspect ratios and overhang lengths in linear cases.

B. Lumped parameter model

Three-dimensional LPM is developed by modifying 2D model described in Ref. 1. Permeances modeling extra flux and leakage paths are added and properly connected to the 2D model. Figure 2 shows part of the modification. Instead of a single path in 2D model, one additional path is added to lead flux originating from the overhang part to the stator tooth through its top. Three permeances, P_2 , P_3 , and P_4 are added to account for this axial flux. As in the 2D case, permanent magnets are modeled as constant potential sources and their permeances are determined by a periodic function of θ .² In the 3D model, the 2D magnet permeance used to represent the internal resistance of one magnet is split into two, P_1 and P_2 . P_2 has the same angular distribution as P_1 (original 2D magnet permeance) and is computed by (1).

$$P_2 = P_1 * (\text{rotor height} - \text{stator height}) / \text{stator height}. \quad (1)$$

Conventional straight-line and circular-arc technique is used for modeling permeances P_3 and P_4 . P_3 models the flux linking to the tooth foot from its top, P_4 models the flux going directly to the tooth stem and equals to zero for a short overhang.

Unlike FEM, where there is a significant computational cost associated with 3D solutions, the addition of 3D permeances in LPM has a much smaller impact. End-to-end leakage permeances can be numerically superposed to existing 2D permeances according to electrical circuit theory. The additional 3D permeances are all linear, and consequently

FIG. 7. The effect of the overhang length on the back EMF, $B_r=0.5$.

FIG. 8. Flux increment of different overhang lengths predicted by LPM.

have a minimal impact on computation time. Computation time consumed in 2D and 3D LPM simulation are of the same order.

III. RESULTS AND DISCUSSION

Figures 3–8 show results over one-half pole pitch, starting from the zero flux (peak back EMF) position. Flux increment is defined as the difference between effective tooth flux predicted by 3D and 2D models divided by that of the 2D model. With this definition, flux increment at 0° is undefined. Magnet overhang is defined as the difference between magnet height and stator height divided by stator height.

Intuitively, several factors such as the size of the slot opening and magnet dead zone, as well as the overhang length, rotor position, and saturation level of stator teeth may influence the overhang effects. The first two factors are examined first. Figure 3 and Fig. 4, respectively, illustrate the influence of the magnet deadzone and slot opening on the flux increment. Both linear and nonlinear cases are investigated. It is seen that the sizes of magnet dead zone and slot opening have no (slight) influence on the flux increment in the linear (highly saturated) cases.

Figure 5 shows how the flux increment changes with magnet overhang. In the linear cases, the flux increment is positive and uniform through the cycle, but it is not proportional to the overhang length. Being independent of the rotor position, the flux increment can be simply related to the overhang length. As shown in Fig. 6, motors with lower aspect ratio require higher order polynomial functions of overhang length to approximate the flux increment. The back EMF (the derivative of flux) is also magnified proportionally. Thus, in the linear case, only magnet overhang and motor aspect ratio influence the flux increment.

Magnetic saturation complicates the flux increment behavior. The nonlinear results shown in Fig. 5 are for a severely saturated design ($B_r=0.71$ T). The flux increment associated with the position where the magnet transition is aligned with a tooth edge is comparable to the linear case, i.e., flux is increased by the introduction of magnet overhang.

TABLE I. Motor dimensions and mesh details.

Gap diameter	19.5 mm
Stator z-height	7.66 mm
Gap	0.25 mm
Element type	8-node brick
Mesh size	1° angular
Gap elements	4 radial
No. nodes	30 000–64 000

As the rotor moves away from this position, however, the flux increment decreases, and near the peak back EMF position (0°), the flux is actually lower than in the 2D case. Figure 7 shows that the detrimental effect of excess overhang occurs even under conditions of moderate saturation ($B_r=0.5$ T). Some overhang (up to 15%) is beneficial to the back EMF its magnitude is increased and shape is preserved. As overhang is increased, the back EMF dip becomes evident. This tendency is more pronounced in highly saturated designs and in configurations with pole pitch longer than slot pitch. The complicated behavior exhibited in the nonlinear case encourages the construction of 3D LPM rather than the simple correction factor applicable to linear cases.

To test the capability of the 3D LPM, flux increments due to different overhang lengths are computed and compared with FEM results. It is observed by comparing Fig. 5 and Fig. 8, the 3D LPM successfully predicts the trends, but tends to overpredict the flux decrement in the vicinity of 0° . This discrepancy may be tolerable for design if the impact on rms back EMF is small. The reason for the discrepancy between LPM and FEM is the subject of current research, and an improved LPM is expected.

IV. CONCLUSION

A typical 8-pole 12-slot spindle motor used in the HDD is used to investigate overhang effects. In the case of mild saturation, magnet overhang always enhances motor performance, increasing back EMF without changing its shape. A series of polynomial functions of overhang length approximate the flux increment of motors with various stator heights and can be used together with 2D FEM in lieu of a full 3D model. Under saturating conditions, however, the simple relationship does not hold. Furthermore, excessive overhang is shown to be detrimental to back EMF. To properly design for magnet overhang, a 3D lumped parameter model using straight-line and circular-arc technique to model axial flux is proposed. Although there is some discrepancy in the magnitude of flux increment at certain rotor positions under severe saturation, the 3D LPM well predicts the trend of flux increment, and seems a better tool for the searching of optimal overhang length in terms of the accuracy and CPU time.

Optimization of coils for detecting initial rotor position in permanent magnet synchronous motor

S. Wakao,^{a)} T. Onuki, K. Tatematsu, and T. Iraha

Department of Electrical, Electronics and Computer Engineering, Waseda University, 3-4-1 Ohkubo Shinjuku-ku, Tokyo 169-8555, Japan

This article describes the shape optimization of detective coils for initial rotor position estimation in the drive system of permanent magnet synchronous motors. The characteristics of magnetic circuits in rotating machinery are very complicated. The magnetic flux distribution in the air gap is nonsinusoidal due to the influence of slots, magnets, and magnetic saturation, etc. By utilizing the slot ripple influence and taking the effects of both magnetic saturation and permanent magnets into consideration, an optimization of the detective coil by means of a genetic algorithm combined with a hybrid finite element and boundary element method is reported. This produces a global optimal solution in a shorter time. © 1998 American Institute of Physics. [S0021-8979(98)50811-0]

I. INTRODUCTION

There is a growing interest in permanent magnet synchronous motors (PMSMs) owing to their high power density and efficiency. Recent efforts are directed toward developing the sensorless drive system for PMSM applications, and various algorithms of rotor-position estimation have been proposed. However, these algorithms, which are generally based on the measurement of terminal voltages and currents of the motor, have some difficulties to detect the rotor position at standstill because the terminal quantities cannot be measured. This results in unstable starting with counter rotation.

To overcome these difficulties in PMSM sensorless drives at standstill, the authors propose to attach additional coils to the motor for detecting the initial rotor position. The proposed detection scheme is based on the voltage induced in the additional coil owing to the small displacement of the rotor with permanent magnets. Applying an impulse input to the armature results in the small displacement of the rotor, and the displacement is transformed into induced voltages. Thus, we can estimate the initial rotor position, and hence sensorless operation follows by using the detected position. It is desirable that the wave form of the induced voltage be a square wave that is suitable for digital processing. This results in both a decrease of the dead zone and an increase in accuracy of the initial rotor-position estimation. This article is aimed at designing the additional coil to obtain the desirable wave form of the induced voltage. Taking the characteristics of magnetic circuits in rotating machinery, e.g., magnetic saturation, into consideration, the authors perform an optimization procedure by means of the genetic algorithm (GA) combined with the hybrid finite element and boundary element (FE-BE) method.

Finally, the numerical example of a concrete model (a four-pole PMSM) is presented to indicate the validity of the proposed optimization procedure.

II. INVESTIGATED SYSTEM

The configuration of the investigated model is shown in Fig. 1. The stator is made of isotropic silicon steel, and the rotor of carbon steel (S45C). Figure 2 represents the $B-H$ curves of the steel. Rare-earth magnets of Sm-Co type are attached to the rotor, and their remanence B_r and coercive force H_c are 0.9 T and 7.0×10^5 A/m, respectively.

The additional coils are thin and placed in the air gap along the stator surface. The voltage induced in the additional coil is amplified and transformed into the rotor position data by a signal processing circuit. A signal processing circuit is usually composed of some logic-integrated circuits of complementary metal-oxide semiconductor type that have two logic states, i.e., H -level and L -level. The boundary between H -level and L -level is called the threshold voltage. The variation of output voltage in the detective coil is illustrated in Fig. 3. If the induced voltage rises slowly, the L -level region becomes larger than that of the fast rise case as in Fig. 3. The dead zone of detective coil increases with the L -level region, which causes the detection capability of the proposed scheme to decrease. Hence it is desirable that the wave form of the induced voltage changes in the rectangular form with rotation. This article describes a shape opti-

FIG. 1. Four-pole permanent magnet synchronous motor.

FIG. 2. B - H curve of steel.

mization procedure to give the detective coil with the above-mentioned characteristics.

III. OPTIMIZATION PROCEDURE

The finite element method (FEM) and the boundary element method (BEM), which have entirely different features from each other, are very useful for numerical analysis of the physical phenomena described by partial differential equations. Both methods seem to be complementary partners and not opponents. Therefore, taking into account of the advantages in these methods, the authors adopt the hybrid FE-BE method as a field calculation tool in this article.¹⁻⁴ By applying the FEM to the rotor and stator regions and the BEM to the air-gap region, a two-dimensional analysis of magnetic field with moving boundaries is naturally implemented without remeshing. This also allows easy consideration of material nonlinearity by the FEM, and enables the precise estimation of air-gap field by the BEM.

The fundamental equation of the magnetic field in terms of the magnetic vector potential A can be obtained as follows:

$$\nabla \times (\nu \nabla \times A) = J_0 + \nabla \times \nu_0 M, \quad (1)$$

where ν is the reluctivity, J is the current density, and M is the magnetization density. The demagnetization characteristic of the permanent magnet is approximated by a straight line, and M is described as

$$M = B - \mu_0 H = B - \mu_0 (B - B_r) (H_c / B_r), \quad (2)$$

where μ is the permeability. The reluctivity is not constant but dependent on the applied magnetic field. Therefore, the distribution of the magnetic field is calculated by the iteration method including a nonlinear analysis. In this article, the

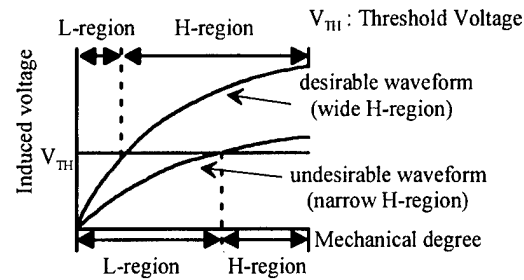

FIG. 3. Wave form of induced voltage.

FIG. 4. Magnetic flux distribution.

FIG. 5. Reluctance torque characteristic.

FIG. 6. Coding for string structure.

FIG. 7. Optimized configuration of additional coil.

Newton-Raphson method⁵ is used in considering the nonlinear characteristics as in Fig. 2. The magnetic field distribution and the reluctance torque characteristic of the investigated model are shown in Figs. 4 and 5, respectively. On the whole, the calculated values of the reluctance torque agree with the experimental data. Finally, regarding the flux distribution in the shaft direction as uniform, we estimate the magnetic flux interlinkage of the detective coil and derive the wave form of the induced voltage by inner field calculation of the BEM.

As regards to a search algorithm, the genetic algorithm (GA) is adopted.^{6,7} The GA is a powerful search method based on probabilistic evolution through generations, which consists of three fundamental operators upon the string structures; reproduction, crossover, and mutation. These string structures called chromosomes represent different design parameters, respectively, (see Fig. 6). Calculating the objective function value, i.e., the length of L -level region, by the hybrid FE-BE method, the GA estimates the fitness of each string structure and creates a new generation from the previous one by the three above-mentioned operators. This results in the survival of the strings that better suit the environment, i.e., the decrease of L -level region, along the future generations.

TABLE I. Optimization results.

FIG. 8. Voltage induced in additional coil.

IV. NUMERICAL RESULTS

An optimization procedure using a GA combined with a hybrid FE-BE method is reported. The initial population of the search has 40 members. The members of the initial population are created by randomly placing the binary code of $\{0, 1\}$ into the bit positions of the chromosomes. Each of the 14 design variables is coded into a four- or five-bit string segment as shown in Fig. 6. Both the roulette wheel and elite technique are implemented for the reproduction operator. The uniform crossover, where each bit in the string has a probability of 0.6 to be swapped, is adopted for the crossover operator. The occurrence probability for mutation is 0.05. The decision on the convergence of solutions is based on the fitness, i.e., the objective function value, of the population. The search is terminated in 937 generations in this example. The whole CPU time required for the optimization procedure is about two days under typical workstation-implementing conditions. The optimization results are shown in Fig. 7 and Table I. Figure 8 indicates the computational results of the normalized voltage wave form induced in the shape-optimized coil. For a comparison, the wave forms of the rectangle-shaped coils with lengths W of one or half pole pitch are also computed and shown in Fig. 8. In this example, setting the threshold voltage of 0.2, we can find the L -level region, i.e., the dead-zone, of the shape-optimized coil is reduced to about 20% of that of the rectangle-shaped coils.

Temperature analysis of induction motors using a hybrid thermal model with distributed heat sources

S. C. Mukhopadhyay^{a)} and S. K. Pal

Department of Electrical Engineering, Jadavpur University, Calcutta 700032, India

The article presents a hybrid thermal model for the accurate estimation of temperature distribution of induction motors. The developed model is a combination of lumped and distributed thermal parameters which are obtained from motor dimensions and other constants such as material density, specific heats, thermal conductivity, etc. The model is especially suited for the derating of induction motors operating under distorted and unbalanced supply condition. The model have been applied to a small (2hp, 415 V, 3-phase) cage rotor induction motor. The performance of the model is confirmed by experimental temperature data from the body and the conductor inside the slots of the motor. © 1998 American Institute of Physics. [S0021-8979(98)23511-0]

I. INTRODUCTION

Prediction of temperature distribution of induction motors is very important to the design engineers as well as motor manufacturers. To have a good knowledge of temperature rise, studies on thermal model of induction motors started quite a long time back. Thermal circuit have been used in the past for electric machinery analysis. An equivalent thermal circuit for non-ventilated induction motors was reported by Kotnik.¹ The different parts of the machine had been considered as lumped parameters interconnected with each other. This just gives some ideas of average temperature rise of motors which was sufficient during that time. Many papers have dealt with the temperature estimation method of the induction motor by using finite element (FE) analysis. In FE analysis usually only a part of stator core and rotor core is considered in the model.² It is difficult to know the temperature distinction along the motor lamination unless a whole model is taken into consideration, particularly under unbalanced voltage operation. This article has described the development of a hybrid thermal model for the analysis of motor temperature distribution. The model can be used during the unbalanced and distorted supply operation of the motors.

II. THERMAL MODEL FORMULATION

The nonsteady conduction equation of heat flow in two dimensions is known to be

$$K_x \frac{\partial^2 t}{\partial x^2} + K_y \frac{\partial^2 t}{\partial y^2} + q^* = \rho C_p \frac{\partial T}{\partial t}, \quad (1)$$

where K_x and K_y are the thermal conductivities along X and Y direction, respectively, q^* is the internal generated heat per unit volume, ρ is the density, and C_p is the specific heat. Equation (1) can be expanded and the equation for the central node, a , in terms of adjacent nodes b , c , d , and e as shown in Fig. 1, can be expressed as

$$\frac{T_b - T_a}{R_{ab}} + \frac{T_c - T_a}{R_{ac}} + \frac{T_d - T_a}{R_{ad}} + \frac{T_e - T_a}{R_{ae}} + q_a = \frac{C_a}{\partial t} (T'_a - T_a), \quad (2)$$

where T_a and T'_a represent current and future temperature of node "a," respectively, q_a is the rate of heat addition to node a , C_a is the thermal capacitance associated with node a ; R_{ab} , R_{ac} , R_{ad} , and R_{ae} represent the thermal resistance between nodes $a-b$, $a-c$, $a-d$, and $a-e$, respectively.

Based on this idea the nodes are assumed throughout the motor cross section, while the thermal capacitances are considered to be lumped at each node and thermal resistances between two consecutive nodes. The thermal model developed for the determination of temperature condition along the motor cross section is shown in Fig. 2. The nodes lying extreme outside represent the ambient temperature and the next inside ones are lying on the motor surface. Adequate number of nodes are assumed to know the detailed temperature distribution of the motor.

The thermal resistances are given by

$$R_t = \frac{1}{K_t} \cdot \frac{L}{A}, \quad (3)$$

where K_t is the thermal conductivity, L is the length of heat flow path and A is the area normal to heat flow path. The thermal conductivities of different materials are chosen as: iron=73, air=0.0241, copper=386, aluminium=202, and

FIG. 1. Nodal network representation for two-dimensional heat flow.

^{a)}Electronic mail: chandra@magstar.ec.t.kanazawa-u.ac.jp

FIG. 2. Thermal model of induction motor.

insulation=0.05. Using Eq. (3) the thermal resistances of the following sections are calculated: (i) frame, (ii) stator core, (iii) stator teeth, (iv) stator slot to stator core, (v) stator slot to stator teeth, (vi) rotor slot to rotor teeth, (vii) rotor slot to rotor core, (viii) rotor teeth, (x) rotor core, and (x) shaft. The following resistances are calculated separately: (i) between frame and ambient, (ii) contact resistance between frame to stator laminations, and (iii) airgap between stator and rotor.

The thermal resistance between frame and ambient (such as R_1, R_{15} , etc. are calculated by $R_{\text{frame}} = \Delta t / P_{\text{node}}$, where Δt is the frame temperature rise over ambient and P_{node} is the power dissipated from each node. The approximate value of Δt is obtained by $\Delta t = W / (AK)$, where W is the total power loss of the machine in W , A is the surface area in m^2 , and K is a constant chosen as $97.1 \text{ W/m}^2/^{\circ}\text{C}$.

Using Eq. (4) the heat dissipated by radiation, W_r , is obtained, where e is relative emissivity, assumed to be 0.9.

$$W_r = 5.72Ae \left[\left(\frac{273 + T_{\text{amb}} + \Delta t}{100} \right)^4 - \left(\frac{273 + T_{\text{amb}}}{100} \right)^4 \right]. \quad (4)$$

The rest power $W_c = W - W_r$ is dissipated by convection. From Eq. (5) Δt is obtained, where D is the outer surface diameter of the machine in meter.

$$W_c = 12.02A \left(\frac{1}{D} \right)^{0.5} (\Delta t)^{1.25}. \quad (5)$$

If Δt obtained from Eq. (5) does not match to that obtained earlier, by slight adjustment Δt is obtained by repeating (4) and (5).

Due to imperfect contact between stator lamination and frame, the thermal resistance is calculated by $R_{1c} = r_{1c} / A_c$, where r_{1c} is thermal contact resistance and depends on the metals involved, the surface roughness, the contact pressure, the materials occupying void spaces and temperature. The value of r_{1c} has been chosen as $0.0005 \text{ m}^2/^{\circ}\text{C/W}$ in the model.

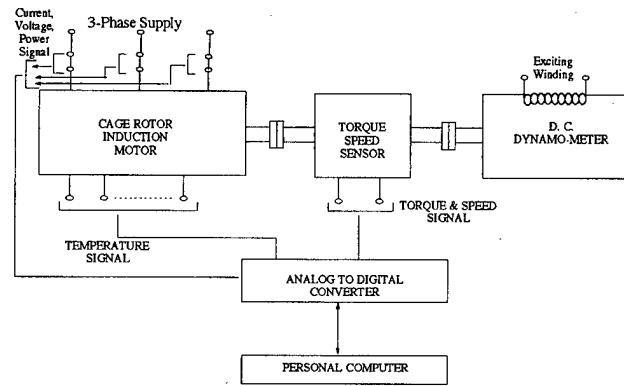

FIG. 3. Experimental setup.

The thermal resistance of airgap between stator and rotor is defined in terms of a dimensionless Nusselt number, N_{Nu} , the airgap length, l_g , and is given by Eq. (6). N_{Nu} to be properly chosen.³

$$R_{\text{ag}} = \frac{l_g}{N_{\text{Nu}} K_{\text{air}} A_{\text{ag}}}. \quad (6)$$

The lumped thermal capacitance at each node is defined as

$$C_a = V_a \rho C_p, \quad (7)$$

where $V_a = \delta x * \delta y * \text{length}$ (δx and δy being the average length between two consecutive nodes along X and Y direction, respectively), ρ is the density, and C_p is the specific heat of the material on which it lies.

In order to model accurately, the heat input to each node must be allocated properly. The dissipated power are: ohmic losses in stator and rotor winding, iron losses in stator core and teeth, flux pulsation loss in stator and rotor teeth, and frictional windage loss. The ohmic losses are calculated from the ohmic resistance and current. Ohmic resistance should be properly adjusted to take into account of temperature rise.

The iron losses are calculated from Eq. (8).

$$p = afB_p^2 + b(\nabla f B_p)^2, \quad (8)$$

where p is the power loss per kg, f is frequency, ∇ is the thickness of lamination in mm, B_p is the peak value of flux density; a and b are two constants and are assumed to be 0.057 and 0.00282 in the model.

In machines with slots both on stator and rotor, the flux density in the teeth varies as the relative position of the teeth varies. The amplitude of the flux fluctuation in the stator teeth is

$$B_{p1} = \frac{\tau_{s2}}{2\tau_{s1}} \cdot \frac{K_{c2} - 1}{K_{c2}} \cdot B_{tm1}, \quad (9)$$

where τ_{s1} and τ_{s2} are the slot pitches of stator and rotor, respectively. K_{c2} is the Carter factor of the rotor, and B_{tm1} is the maximum value of flux density in the middle of the tooth.

The frequency is given by $f_1 = Q_2^* (\text{rpm}/60)$, where Q_2 is the number of slots in the rotor. For the rotor teeth the indices 1 and 2 should be interchanged.

The pulsation loss in watts per unit weight of the teeth is given by

FIG. 4. Thermal characteristic (a) at continuous running with short time load, (b) steady-state temperature with power output.

$$P_p = b(\nabla f B_p)^2. \quad (10)$$

The mechanical loss due to friction of the bearing and windage loss are

$$P_{F+W} = 5.4 \times 10^5 (\text{rpm})^{0.7} P_R, \quad (11)$$

where P_R is the rated power of the machine in watts.

After calculating all the thermal resistances and capacitances and allocating the losses to each node, the temperature of each node is calculated by

$$t'_i = t_i + \partial\tau \left(\sum_j \frac{t'_j - t'_i}{R_{ij}C_i} + \frac{q_i}{C_i} \right). \quad (12)$$

Starting values of all the nodes are taken to be equal to ambient temperature. The time step $\partial\tau$ should be critically selected so that

$$\partial\tau \leq \left[\frac{1}{\sum_{i=1}^n 1/(R_{ij}C_i)_{\min}} \right]. \quad (13)$$

The solution is assumed to reach steady-state values when

$$|T(j)_{n+1} - T(j)_n| \leq \epsilon \quad (14)$$

is satisfied for each and every node, where ϵ is a convergence criterion.

III. PERFORMANCE OF THE MODEL AND EXPERIMENTAL VERIFICATION

The model is applied to a small 4 pole motor. The detailed specifications of the motor are: Three-phase cage-rotor induction motor; power output=2hp, voltage=415 V, current=3.2 A, frequency=50 Hz, speed=1425 rpm, insulation=Class B, no of stator slots=36, no of rotor slots=44, stator outer diameter=190 mm, rotor outer diameter=114.5 mm, core length=100 mm, stator resistance per phase=6.8 Ω , rotor resistance referred to stator=6.4 Ω .

The experiments are conducted using the setup as shown in Fig. 3. The load on the motor is changed by varying the excitation. The surface and slot temperatures are measured by temperature sensors.

Figure 4(a) shows the simulated and experimental thermal characteristic at continuous running with short time load. Figure 4(b) shows the variation of steady-state temperature of surface and slot with power output. It is seen that the difference of the experimental and simulated values are less than 2 °C.

IV. CONCLUSION

This article has reported the development of a thermal model for the temperature analysis of induction motors. The model is based on distributed thermal resistances and capacitances with properly allocated heat sources to each node. The model can predict both steady state and transient temperature rise of motors. Predicted results were compared with measurements showing good agreement, thus proving the validity of the model.

Some chaotic properties of a six-dimensional nonlinear dynamic system are investigated. Equations describing the system are based on the equivalent circuit of a magnetic frequency tripler. Numerical solutions are obtained using the fourth-order Runge–Kutta algorithm. Simulation results reveal the presence of Hopf and a period-doubling bifurcations. Phase space projections at points before and after bifurcations show the existence of three symmetrical and four asymmetric regions. Poincaré maps reveal six different chaotic attractors within the asymmetric regions. The correlation dimension of the sea horse attractor is found to be 2.37. © 1998 American Institute of Physics. [S0021-8979(98)23611-5]

I. INTRODUCTION

Studies of bifurcation phenomena in the Van der Pol–Duffing oscillator as well as in two coupled Duffing oscillators were described recently in Refs. 1 and 2. A similar behavior can be observed in an electromagnetic circuit of a frequency tripler. This circuit can be described as a six-dimensional nonlinear dynamic system and it can be simulated on a computer using the fourth-order Runge–Kutta algorithm. In the previous attempt to depict bifurcation diagrams of the magnetic frequency tripler using voltage of the saturable reactor as a parameter, a period-doubling (PD) bifurcation and the presence of a chaotic attractor were revealed. These results were presented in Refs. 3 and 4.

This article describes equations of state for a six-dimensional nonlinear system based on the equivalent circuit of a magnetic frequency tripler. Numerical solution of these equations enable further analysis. Characteristic sequences of transitions are studied using bifurcation diagram. The phase space projections obtained from the numerical solution verify existence of chaotic attractors in the regions after bifurcations as well as the presence of symmetry in the phase space. Then, the correlation dimension of the phase space trajectory is performed in the region of sea horse attractor.

II. EQUATIONS OF STATE

The six-dimensional nonlinear system described in this article is obtained from the equivalent circuit of a magnetic frequency tripler with series-connected reactors.⁵ Figure 1 shows the six-dimensional nonlinear system for computer simulations. This system was presented in detail previously in Refs. 3 and 4. Here, we bring only its short description. If

magnetizing characteristics of the saturable reactors are approximated by third-order polynomials, equations of state for this system become

$$\begin{aligned}\dot{x}_1 &= -k_1 x_1 - k_2 x_2 + f \sin \tau, \\ \dot{x}_2 &= k_3 x_1 - \alpha_1 x_3 - \beta_1 x_3^3 - \alpha_2 x_4, \\ \dot{x}_3 &= k_4 (x_2 + x_6), \\ \dot{x}_4 &= k_5 (x_2 - x_6), \\ \dot{x}_5 &= k_6 x_6, \\ \dot{x}_6 &= \alpha_{20} x_4 - \alpha_{10} x_3 - \beta_{11} x_3^3 - \alpha_{00} x_5 - \beta_{00} x_5^3 - k_7 x_6,\end{aligned}\quad (1)$$

where $(x_1, x_2, \dots, x_6, \tau) \in R^6 \times S^1, \tau \in S^1$.

These equations are solved numerically using the fourth-order Runge–Kutta algorithm with double precision. The system is iterated 36 000 times (200 periods, 400π). A step size of 3.4906585×10^{-2} ($2\pi/180$) ensured converged numerical results.

III. BIFURCATION DIAGRAM

Bifurcation diagrams are obtained by setting the coefficient k_4 (voltage across C_{in} and C_o) as a parameter and by plotting solutions for x_5 obtained at 2π radian intervals. In order to exclude initial transient solutions for $0 \leq \tau < 100\pi$ are ignored, and then, solutions for $100\pi \leq \tau \leq 400\pi$ are plotted.

Figure 2 shows bifurcation diagram obtained by incrementing parameter k_4 by 0.002 units. It can be seen from the

FIG. 1. Six-dimensional nonlinear system for computer simulations.

^{a)}Electronic mail: t-sutani@neptune.kanazawa-it.ac.jp

FIG. 2. Bifurcation diagram with $\alpha_{1i} = \alpha_{10} = \alpha_{00} = 0$, $\alpha_{2i} = 5.0 \times 10^{-6}$, $\alpha_{20} = 6.0 \times 10^{-6}$, $\beta_{1i} = 1.5$, $\beta_{00} = 1.8$, $\beta_{10} = 1.3$, $f = 12.5$, $k_1 = 0.05$, $k_2 = 0.011$, $k_3 = 20.0$, $k_5 = 0.2$, $k_6 = k_7 = 0.5$, $x_{10} = 1.1$, $x_{20} = 1.0$, $x_{30} = 5.0$, $x_{40} = 2.0$, $x_{50} = 3.0$, and $x_{60} = 4.0$.

diagram that the region $k_4 < 0.1$ is chaotic. This chaotic region is followed by a sequence of period-one, period-two, and period-one solutions. The Hopf bifurcation takes place at $k_4 = 0.3$ followed by another band of period-one solutions. The PD bifurcation occurs at $k_4 = 0.448$, followed by another chaotic region. Later, for $0.63 < k_4 < 0.79$, period-one solutions dominate except for a few chaotic regions appearing sporadically. The bifurcation diagram converges finally to stable period-one solutions for $k_4 > 0.8$.

IV. PHASE SPACE PORTRAITS

All period-one solutions of the analyzed system return generally identical phase space trajectories if the initial transients are ignored. Phase space trajectories for chaotic solutions, on the other hand, assume several characteristic shapes. Figure 3 shows some examples of the phase space diagrams obtained for $100\pi < \tau \leq 102\pi$ before and after Hopf bifurcation points.

The orbit shown in Fig. 3(a) is obtained for $k_4 = 0.272$. This orbit is asymmetric. Figure 3(b) shows the orbit for the parameter k_4 increased to 0.284. The resulting orbit becomes symmetrical with respect to origin, i.e., $f(-x) = -f(x)$. Figure 3(c) shows an asymmetric orbit at an upper symmetry-breaking (SB) point which occurs for $k_4 = 0.298$. The transition from the upper SB point leads to the onset of the Hopf bifurcation. This transition can be identified as Hopf bifurcation following Sparrow's work on the Lorenz system⁶ and Kozłowski's work on two-coupled Duffing oscillators. From there, it is concluded that Hopf bifurcation is always accompanied by SB in the phase space diagram.

Figure 4 shows examples of orbital trajectories from the third and the widest region on the bifurcation diagram in which symmetry is maintained. Figure 4(b) shows the orbit

FIG. 3. Phase space projections: (a) $k_4 = 0.272$, (b) $k_4 = 0.284$, and (c) $k_4 = 0.298$.

FIG. 4. Phase space projections: (a) $k_4 = 0.320$, (b) $k_4 = 0.360$, and (c) $k_4 = 0.390$.

at $k_4 = 0.360$ with its typical shape for this symmetrical region. In comparison with Fig. 3(b), the orbit has similar inverse structure except that this time it has more loops which, in turn, indicates the presence of higher harmonics. Further, symmetric trajectories become asymmetric at $k_4 = 0.390$, but here the SB point does not precede a PD bifurcation.

In the analyzed system, there are no further symmetrical regions observed for $k_4 \geq 0.390$. In such a case, a question arises whether phase space portraits at points prior and after PD bifurcation present the same asymmetric structure. In order to clarify this question, orbital projections of the phase space are investigated around this PD bifurcation point. Figure 5(a) shows an orbit for τ between 100π and 102π for $k_4 = 0.4465$, i.e., just prior the bifurcation. This orbit is asymmetric. Figure 5(b) shows an orbit for $k_4 = 0.4466$. The orbit also appears to be asymmetric. However, comparison of the shape of orbits prior to bifurcation with that after the bifurcation reveals that they are in central symmetry with each other with respect to origin. For the first time it is shown that a reversal of phase space occurs in order to preserve asymmetry at the PD bifurcation point.

V. CHAOTIC ATTRACTORS

There have been several types of chaotic attractors defined in multidimensional dynamic systems.⁷ In order to find the types of attractors existing in the frequency tripler analyzed in this paper, Poincaré maps are constructed for chaotic regions identified previously on the bifurcation diagram. Six maps, consisting of 2000 periods ($\tau = 4000\pi$) each, are shown in Figs. 6(a)–6(f). These maps are obtained for $k_4 = 0.05, 0.16, 0.30, 0.50, 0.59$, and 0.74 , respectively. Figures 6(a) and 6(b) show two slightly different Poincaré sets but both displaying characteristics of hyperchaos.⁸ Figure 6(c) shows a chaotic attractor obtained at a point after Hopf bifurcation. This attractor does not represent a limit cycle and

FIG. 5. Phase space projections: (a) $k_4 = 0.4465$ and (b) $k_4 = 0.4466$.

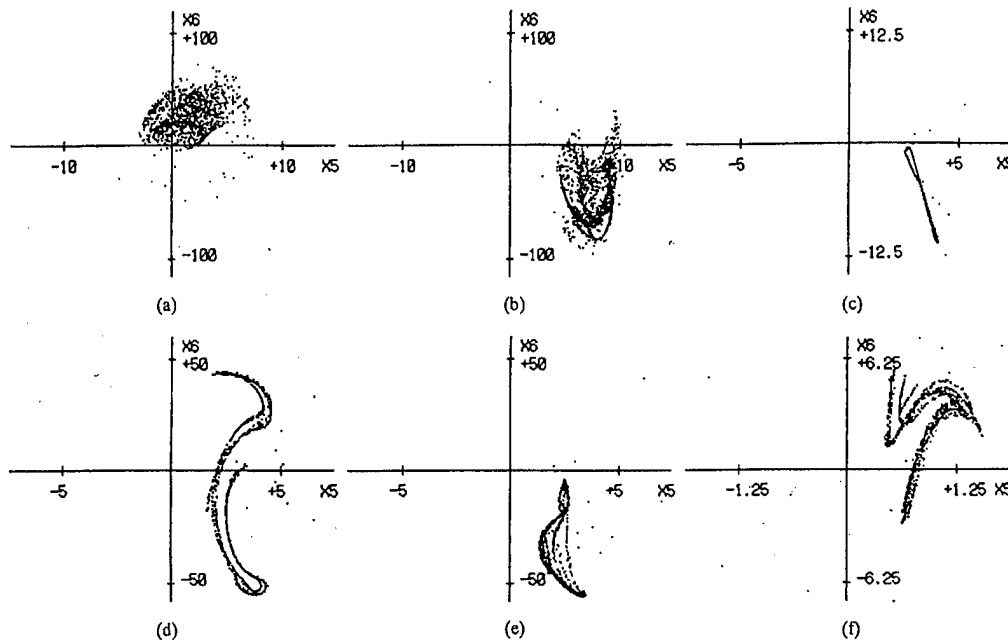

FIG. 6. Two hyperchaos: (a) $k_4=0.05$ and (b) $k_4=0.16$, and four chaotic attractors: (c) $k_4=0.30$, (d) $k_4=0.50$, (e) $k_4=0.59$, and (f) $k_4=0.74$.

it can be called a string attractor. Figure 6(d) shows a shape of the before-presented sea horse attractor. The harp attractor is also identified within the region of the PD cascade and it is shown in Fig. 6(e). It should be noted that the harp attractor is not a part of the sea horse attractor, as it may appear, but it is another type of attractor. Figure 6(f) shows a sparrow attractor which appears in the narrow chaotic regions after the PD cascade. In summary, two hyperchaos and four other chaotic attractors are identified in the six-dimensional system investigated in this article.

In order to determine dimensionality of a dynamic system the correlation method is used. Following the work of Grassberger and Procaccia,⁹ the correlation dimension D_c can be defined as

$$D_c = \lim_{\delta \rightarrow 0} [\log C(\delta) / \log \delta], \quad (2)$$

where $C(\delta)$ is a correlation integral as a function of the diameter δ , of the phase space volume element in which the integral is evaluated.

Computations of the correlation dimension for the frequency tripler are performed on the phase space trajectory assuming the shape of a sea horse attractor on the Poincaré map. As the result, the value of $D_c=2.37$ is obtained. This outcome indicates that our original six-dimensional system can be described with a substantially smaller number of variables, possibly as low as three.

VI. CONCLUSION

Bifurcation phenomena and chaotic attractors in a six-dimensional nonlinear system based on the equivalent circuit of a magnetic frequency tripler have been analyzed in this article. The main results are as follows.

- (1) Phase space projections are asymmetric at regions where hyperchaos, period-two solutions, the Hopf bifurcation and the period-doubling bifurcation occur.
- (2) The occurrence of the Hopf bifurcation is accompanied by symmetry breaking of the phase space trajectory.
- (3) The phase space trajectory reverses at the point of the period-doubling bifurcation to preserve asymmetry.
- (4) The existence of two hyperchaos and four chaotic attractors is found in the system.
- (5) The correlation dimension of the sea horse attractor is 2.37.

Our next subjects are investigation on mechanics of development of chaotic attractors and controlling chaos in the six-dimensional system.

Neutron diffuse scattering in the form of rod-like features has been observed in single crystals of the layered CMR material $\text{La}_{2-2x}\text{Sr}_{1+2x}\text{Mn}_2\text{O}_7$ ($x=0.4, 0.36$), consistent with the presence of 2D ferromagnetic spin correlations. These diffuse features are observed over a wide temperature region. However, their coherence length does not appear to diverge at T_C , although there is evidence of the development of three-dimensional correlations around ferromagnetic reflections of the 3D-ordered magnetic structure close to T_C . Quasi-elastic neutron scattering on a ceramic sample of $x=0.3$ shows that the lifetime of these ferromagnetic correlations increases at $T \rightarrow T_C$. They exhibit a spin-diffusion constant above T_C of $\sim 5 \text{ meV } \text{\AA}^2$, much lower than that reported for $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$. We discuss the relationship of these magnetic correlations to models of the ferromagnetic transition in CMR compounds. © 1998 American Institute of Physics.

[S0021-8979(98)43211-0]

The close interplay among charge, spin, and lattice degrees of freedom in the colossal magnetoresistive (CMR) manganite oxides is widely believed to play an important role in the mechanism of transport in these itinerant ferromagnets. Among the current models of transport in the three-dimensional perovskite materials is that magnetic polarons—mobile lattice distortions carrying spin—are the fundamental charge-carrying entity, at least above the Curie temperature (T_C).^{1,2} Indeed, localized lattice distortions have been observed above and below T_C ,^{3,4} in the (La, Ca) MnO_3 perovskite system. DeTeresa *et al.* have extended this work by inferring that these lattice distortions carry spin (magnetic polarons) from recent in-field small angle neutron scattering (SANS) experiments on the perovskite $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$.⁵

While current attention is centered on perovskite manganites, the discovery of layered compounds $\text{La}_{2-2x}\text{Sr}_{1+2x}\text{Mn}_2\text{O}_7$ as another class of CMR oxides provides a rich opportunity to explore structure-property relationships on varying length and time scales in reduced dimensions. The material of interest, is comprised of perovskite bi-layers of corner-linked MnO_6 octahedra forming infinite sheets. Bi-layers of (La, Sr) MnO_3 are separated

along the c -axis by insulating (La, Sr)O layers. We have shown that although below T_C Mn-spins order ferromagnetically within the ab -plane⁶ in a certain compositional range, a competition between super- and double-exchange may result to a canting of Mn-spins between adjacent ferromagnetic sheets, within the perovskite bi-layer.⁷ There is evidence to show that this competition may be reflected within ferromagnetic correlations above T_C , as reported recently by Osborn *et al.*⁸ Perring *et al.* also report that weak antiferromagnetic and ferromagnetic spin fluctuations coexist in these layered materials above T_C .⁹ Clearly, understanding both long and short range magnetism—structure and dynamics—is an essential ingredient in developing a coherent picture of the physics of this class of transition metal oxides.

In this paper we report neutron scattering results from single crystals with $x=0.4$ and 0.36 that demonstrate that 2D ferromagnetic correlations exist in these layered CMR materials, as high as $2.8T_C$. Their size increases as $T \rightarrow T_C$ reaching a size of $\sim 10 \text{ \AA}$ at T_C . The coherence length of these ferromagnetic correlations does not appear to diverge at T_C . Quasielastic neutron scattering from a polycrystalline x

=0.3 sample, reproduce the single crystal results and find a spin diffusion constant of $5 \text{ meV } \text{\AA}^2$, lower than that recently determined for the 3D perovskite materials.

Single crystals of $\text{La}_{2-2x}\text{Sr}_{1+2x}\text{Mn}_2\text{O}_7$ were melt-grown in flowing 100% O_2 in a floating zone optical image furnace (NEC SC-M15HD). The crystals were characterized using inductively coupled plasma spectroscopy (ICP), d.c. magnetization, and resistivity. Two single crystals were prepared and characterized by these methods; ICP measurement of their composition was determined to be consistent with a doping of $x=0.40(1)$ ($\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$) and $x=0.36(1)$ ($\text{La}_{1.28}\text{Sr}_{1.72}\text{Mn}_2\text{O}_7$). These samples exhibit transitions from a paramagnetic insulator (PI) to a ferromagnetic metal (FM) at 133 K for $x=0.36$ and 116 K for $x=0.4$. Diffraction data were obtained as a function of temperature from these single crystals, using the neutron time-of-flight single crystal diffractometer (SCD) located at the Manuel Lujan Jr., Neutron Scattering Center (MLNSC) at the Los Alamos National Laboratory. Quasi-elastic neutron scattering data were measured as a function of temperature from a polycrystalline sample with $x=0.3$ ($\text{La}_{1.4}\text{Sr}_{1.6}\text{Mn}_2\text{O}_7$) synthesized via standard ceramic techniques exhibiting coupled PI to FM transitions at 116 K, using the time-of-flight chopper spectrometer PHAROS,¹⁰ also located at the MLNSC. Data were recorded using an incident energy of 12.1 meV, except for data measured at 115 K where incident energies of 12.1 and 8.1 meV were used to extend the Q range of the measurement. Neutron powder diffraction data were measured as a function of temperature from 20–300 K, using the Special Environment Powder Diffractometer (SEPD)¹¹ at the Intense Pulsed Neutron Source at the Argonne National Laboratory.

Single crystal time-of-flight neutron diffraction is ideally suited for the broad survey of reciprocal space for both Bragg reflections (long range structure) and also diffuse scattering which reflects structural features on a local scale. For both $x=0.36$ and $x=0.4$ single crystals, we observe a diffuse rod-like feature along c^* centered at $(0,1,0)$ and $(1,0,0)$. An example of these rod-like features is shown in Fig. 1, measured at 120 K from the $x=0.36$ crystal. The diffuse scattering is strongly temperature dependent, becoming more intense as $T \rightarrow T_C$, while below T_C it decreases, consistent with scattering from magnetic correlations. For the $x=0.4$ crystal we do observe rod-like features for higher orders of h and k [$(h,0,0)$ or $(0,k,0)$ with h or k as high as 7], where the magnetic form factor is expected to decrease substantially the magnetic scattering. These features have a smaller FWHM than the scattering at $h=1$, or $k=1$, suggesting that there is an additional nuclear component to the observed magnetic scattering. This nuclear scattering may arise from a low density of perovskite intergrowths in the crystal as proposed by Potter *et al.*¹² and also observed in high resolution electron microscopy.¹³ For the $x=0.36$ crystal we observed no diffuse scattering at higher orders of h and k , suggesting a significantly lower concentration of intergrowths than in the $x=0.4$ crystal.

Figure 2 shows the variation of the intensity of the magnetic rod scattering in both $x=0.36$ and $x=0.4$ crystals as a function of temperature. These values were obtained by fitting data perpendicular to the rod, along the $[010]$ direction,

FIG. 1. Time-of-flight neutron diffraction data measured from a single crystal of $\text{La}_{1.28}\text{Sr}_{1.72}\text{Mn}_2\text{O}_7$ at 120 K. The observed scattering is shown as a section through reciprocal space (a) perpendicular to $[100]$ and (b) perpendicular to $[001]$. The small peak just below the (011) reflection corresponds to a much smaller second crystal in the sample with a relative intensity of the main (011) reflection of $1/5000$.

with a Lorentzian function and accounting for the nuclear scattering with a narrower Lorentzian with its width fixed at a value determined at 20 K. We find that the intensity of the magnetic diffuse scattering increases as $T \rightarrow T_C$ from above, while below T_C its intensity decreases, vanishing for $T < 0.5T_C$. That this scattering appears as a diffuse rod along c^* and with a finite width along $[h00]$ or $[0k0]$, clearly shows that the spin correlations are 2D. We find that these modulations are ferromagnetic but do not strictly obey a $\cos^2(\pi\Delta z/l)$ dependence (where Δz is the difference of the fractional z coordinate between neighboring Mn atoms); we have proposed a model where these modulations are described in terms of spin-canting in these ferromagnetic correlations resulting from a competition between super- and double-exchange which is reported elsewhere.⁸ On Fig. 2 we also show the variation of intensity of the $(0,1,1)$ ferromag-

FIG. 2. Temperature dependence of diffuse scattering intensity at (0,1,0) and the intensity of the ferromagnetic (0,1,1) measured from single crystals of $x=0.4$ and 0.36 . The intensity of the (0,1,1) reflection has been normalized to its intensity measured at 300 K.

netic reflection as a function of temperature. This demonstrates that peak in the intensity of the ferromagnetic 2D fluctuations is correlated with the onset of 3D magnetic ordering. The observed ferromagnetic reflections below T_C were consistent with ordered Mn spins aligned ferromagnetically within the ab plane as reported previously.⁶

The coherence length of the ferromagnetic correlations within the perovskite bilayers, ξ_{2D} , is $\sim 4-5$ Å at 300 K, and increases to ~ 10 Å at T_C . Surprisingly ξ_{2D} does not appear to diverge at T_C (see Fig. 3). It is unclear where the critical region for these 2D ferromagnetic correlations lies,

FIG. 3. The planar coherence length ξ_{2D} as a function of temperature.

however, from a more detailed study on the same $x=0.4$ crystal we find that power law scaling of ξ_{2D} suggests a much lower critical temperature for these correlations than actually observed; a $T_C^{2D}=98$ K is obtained using a mean field exponent $\nu=0.5$, or a $T_C^{2D}=63$ K for a 2D-Ising exponent of $\nu=1$.⁸ Interestingly, measurement of the critical scattering close to the (004) ferromagnetic reflection suggests that there is a buildup of three-dimensional correlations below 120 K resulting in a coherence length that appears to diverge at T_C .⁸ These data suggest that there may be a cross-over close to T_C from 2D to 3D critical scaling. However, we also note that in the same temperature region we have reported significant electron-phonon coupling in these materials.⁶ As discussed below, these localized lattice distortions

FIG. 4. Inelastic neutron data in Q, ω space measured at 128 K (a) and 30 K (b) using an incident neutron energy of 12.1 meV. The same data measured at 128 K (c) and 30 K (d) plotted as a function of energy integrated over the accessible Q -range of this measurement. See text for details.

FIG. 5. (a) Temperature dependent resistivity and magnetization (determined from full profile Rietveld refinement of neutron powder data) from the polycrystalline sample $\text{La}_{1.4}\text{Sr}_{1.6}\text{Mn}_2\text{O}_7$, (b) integrated intensity of the quasi-elastic Lorentzian component, and (c) coherence length as a function of reduced temperature T/T_C . In (c) the dashed lines are a fit to a power law function. Magnetic reflections from the $x=0.3$ sample were consistent with a ferromagnetic alignment of Mn spins in the a - b plane.⁶

tions may contribute to the lack of divergence in the 2D coherence length. Theoretical considerations suggest that this coupling arises from local Jahn-Teller effects in these mixed valent materials.^{1,2}

To investigate the spin dynamics of these 2D ferromagnetic correlations we have measured quasi-elastic neutron scattering from a large polycrystalline sample of $x=0.3$. (The need for a large sample mass to yield sufficient signal-to-noise prohibited the use of a single crystal specimen for this experiment.) We have deliberately selected a Q, ω range to measure ferromagnetic scattering as l or $Q \rightarrow 0$ without the measurement being perturbed by spin waves and 3D spin correlations at lower Q . Figures 4(a) and 4(b) show data measured at 128 and 30 K in Q, ω space, while panels (c) and (d) show the same data, integrated over the accessible Q range, as a function of energy. On panels (c) and (d) we show a fit to the elastic incoherent peak using a Gaussian function with a fixed FWHM that reflects the resolution of the spectrometer (dashed line). At 30 K we find no significant deviations from the fit, as seen in Fig. 4(d). This contrasts with the scattering at higher temperatures, and especially close to T_C , where we find an additional broad Lorentzian component superimposed on the Gaussian elastic

FIG. 6. The Q -dependence of the Lorentzian quasielastic width (Γ) at 115 K measured from a ceramic sample of $\text{La}_{1.4}\text{Sr}_{1.6}\text{Mn}_2\text{O}_7$. The dashed line represents a fit to $\Gamma = \Lambda Q^2$, while the solid line represents the behavior observed in $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ reported by Lynn *et al.*¹⁵

incoherent peak. This feature is clearly shown in Figs. 4(a) and 4(c). The intensity of the Lorentzian component diverges as $Q \rightarrow 0$, as expected for ferromagnetic correlations.

Both quantitatively and qualitatively this ceramic $x=0.3$ sample behaves similarly to the single crystals discussed above. A broad Lorentzian component is observed as high as $2.8T_C$ [Fig. 5(b)], while with decreasing temperature and approaching T_C , the intensity of the quasi-elastic scattering increases and reaches a maximum at T_C . Below T_C the quasi-elastic scattering decreases linearly with temperature suggesting that it may result from soft c -axis spin wave scattering.¹⁴ The peak in the quasi-elastic scattering at T_C strongly correlates with a sharp decrease in the resistivity of the sample, and the development of three-dimensional ordering of Mn spins determined from neutron powder diffraction, as shown in Fig. 5(a). These observations resemble those reported from inelastic scattering experiments on three-dimensional perovskite materials.¹⁵ The spatial extent of the ferromagnetic correlations—computed from the Q dependence of the Lorentzian signal—yields an overall ξ of $\sim 5 \text{ \AA}$ ($\sim 1.30a$), increasing to $\sim 12 \text{ \AA}$ at T_C ($\sim 3.1a$), similar to that found for the single crystal samples described above [see Fig. 5(c)].

The lifetime of these ferromagnetic correlations, obtained from the width of the quasi-elastic scattering integrated over the accessible Q range of the measurement, increases $T \rightarrow T_C$, reaching a value of $1.1(1) \times 10^{-11} \text{ s}$ at T_C . Interestingly like the correlation length, the lifetime does not diverge suggesting that even close to T_C , there are 2D ferromagnetic spins that are rapidly fluctuating [see Fig. 5(c)]. Lynn *et al.*¹⁵ have suggested that the magnetic transition in CMR perovskites is unusual as the spin waves stiffness constant D does not collapse close to T_C . Instead they describe the magnetic transition in the perovskite $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ in terms of spin-diffusion due to slow polaronic hopping of e_g carriers with a spin diffusion constant, Λ , of 30 meV \AA^2 , a quantity that is analogous to the spin-stiffness constant for a magnetically ordered system. From the Q dependence of the Lorentzian width we estimate a spin-diffusion constant $\Lambda \sim 5 \text{ meV \AA}^2$ at 115 K for our sample (see Fig. 6), a value substantially lower than the perovskite material

(30 meV Å²). Presumably, this reduced Λ is a consequence of the low dimensionality of these naturally layered manganites.

The results presented here clearly demonstrate that in these naturally layered materials 2D ferromagnetic correlations exist at temperatures as high as $\sim 2.8 T_C$. As $T \rightarrow T_C$, their size and lifetime increases but these quantities do not appear to diverge at T_C . Clearly there is a need to reconcile the behavior of these ferromagnetic correlations with the 3D ferromagnetic transition at T_C , where critical behavior and a divergent coherence length is observed about magnetic reflections. The data support a model where the 3D magnetic transition interrupts 2D fluctuations that would otherwise order over a long range at a lower T_C (see also Ref. 8). That the measured T_C occurs at a higher temperature than the estimate of T_C^{2D} suggests that at a critical size ξ_{2D} , Mn spins in adjacent perovskite bilayers may start ordering ferromagnetically in three dimensions. This implies a crossover to 3D critical scaling close to T_C . Indeed the underlying physics of these 2D ferromagnetic correlations may be competing antiferromagnetic super-exchange and ferromagnetic double-exchange; in a previous paper we have reported that this competition may result in a canted Type-A ferromagnetic structure in $x=0.4$ below T_C .⁷ As pointed out by Osborn *et al.* these ferromagnetic correlations may arise from the same competition above T_C .⁸

Alternatively the observation of nondivergent ferromagnetic correlations over a wide temperature region, may lend support to the small polaron model put forward to explain CMR in the manganite perovskites.^{1,2} Röder *et al.*¹ have calculated the magnetic behavior of localized phenomena such as Jahn–Teller polarons associated with localized e_g carriers and argue that the magnetic transition in the CMR manganites is accompanied by a crossover of length scales from a quasi-self-trapped small polaron to a large polaronic state below T_C . At T_C their calculation predicts a magnetic coherence length of ~ 3 –4 Mn sites or ~ 12 –16 Å. As magnetic polarons have a finite size, their coherence length is not necessarily expected to diverge as in a second-order magnetic transition. That is, the coherence length of the 2D magnetic correlations may be constrained by the lattice degrees of freedom (localized Jahn–Teller effects), which are in turn influenced by the electronic state. Our values of ξ_{2D} are in reasonable agreement with the prediction of Röder *et al.* and the size measurements of magneto-elastic polarons by DeTeresa *et al.* in $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$,⁵ while the lower value of Λ observed here may reflect polaronic mobility in reduced dimensions compared to the 3D octahedral network of perovskite materials. However, since the degree of electron-phonon coupling (via the Jahn–Teller effect) and T_C are closely coupled in the CMR materials,^{1,2,16} the difference between the two possible explanations put forward here may be subtle.

In conclusion, we have demonstrated the existence of 2D ferromagnetic correlations in layered CMR materials over a wide temperature range, with a coherence length ξ_{2D} and lifetime that do not diverge at T_C . These 2D ferromagnetic correlations accompany the ferromagnetic transition at T_C , which appears to exhibit critical scattering and a divergent coherence length. Quasi-elastic neutron scattering shows these ferromagnetic correlations still fluctuate rapidly close to T_C , while the spin diffusion constant is much lower than the perovskite materials. Importantly, the naturally layered manganites provide a unique opportunity to examine in detail the mechanism of this crossover between 2D and 3D magnetism.

Experiments on three double-layer ($n=2$) Ruddlesden–Popper (RP) systems are reported. Doping $\text{Sr}_{1.8}\text{La}_{1.2}\text{Mn}_2\text{O}_7$ ($T_c=126$ K) with Nd to form $\text{Sr}_{1.8}\text{La}_{1.2-x}\text{Nd}_x\text{Mn}_2\text{O}_7$ leads to a reduction in Curie temperature for low doping levels ($x=0.2$), and to behavior reminiscent of $\text{Sr}_{1.8}\text{Nd}_{1.2}\text{Mn}_2\text{O}_7$ for $x\geq 0.7$. This suggests that it may be possible to control the temperature of maximum magnetoresistance chemically in these phases. The application of pressure ($0 < P/\text{GPa} \leq 1.8$) is shown to modify the magnetotransport properties of $\text{Sr}_2\text{NdMn}_2\text{O}_7$ to resemble those of $\text{Sr}_{1.9}\text{Nd}_{1.1}\text{Mn}_2\text{O}_7$. The changes can be explained by considering the relative strength of ferromagnetic and antiferromagnetic interactions within the material. Finally, the need for careful phase analysis of $n=2$ RP materials is demonstrated by the misleading magnetization data recorded for a sample of $\text{Sr}_{1.8}\text{Sm}_{1.2}\text{Mn}_2\text{O}_7$ containing $\sim 2.8\%$ of an $n=\infty$ perovskite phase. © 1998 American Institute of Physics. I. INTRODUCTION

Compounds of manganese have played a central role in recent studies of the magnetotransport properties of mixed metal oxides. It has been shown that the electrical resistivity of oxides containing Mn in a nonintegral oxidation state ($\text{Mn}^{3+/4+}$) can decrease dramatically in an applied magnetic field, an observation that may lead to applications in the area of data storage. The effect has been most widely studied^{1,2} in perovskites of the general form $\text{Ln}_{1-x}\text{A}_x\text{MnO}_3$, where the presence of both lanthanide (Ln) and alkaline earth (A) cations results in the adoption of a mixed-valence state by the Mn cation. Perovskite can be regarded as the $n=\infty$ member of the Ruddlesden–Popper (RP)³ family of compounds $(\text{Ln}, \text{A})_{n+1}\text{B}_n\text{O}_{3n+1}$, with the K_2NiF_4 structure being at the opposite ($n=1$) extreme (Fig. 1). RP phases can be considered to consist of perovskite-like blocks of vertex sharing BO_6 octahedra which extend to infinity in the xy plane and have a thickness of n octahedra parallel to the z axis; neighboring blocks are separated by a rock-salt layer such that the overall composition can be described as $[(\text{Ln}, \text{A})\text{BO}_3]_n(\text{Ln}, \text{A})\text{O}$. Following the observation of colossal magnetoresistance (CMR) in $n=\infty$ RP phases, the electronic properties of other members of the series have been studied. CMR is not observed in samples of the $n=1$ system $\text{Sr}_{2-x}\text{La}_x\text{MnO}_4$ which, for $x\sim 0.5$, show charge ordering on the Mn sublattice.^{4–7} However, CMR has been detected around the Curie temperature (126 K)⁸ of the $n=2$ (Fig. 1) composition $\text{Sr}_{1.8}\text{La}_{1.2}\text{Mn}_2\text{O}_7$, which does not show charge ordering. The majority of the data collected to date for $n=1, 2$, and ∞ suggest that CMR is incompatible with charge ordering on the Mn sublattice, and that it is closely linked to the appearance of a spontaneous magnetization in the sample. There are, however, a number of ex-

ceptions to this sweeping generalisation. $\text{Sr}_{2-x}\text{Nd}_{1+x}\text{Mn}_2\text{O}_7$, for example, shows^{9,10} CMR in the absence of a spontaneous magnetization. Studies of this system have demonstrated that the nature and behavior of the sample are very sensitive to the conditions used in the chemical synthesis.¹¹ More specifically, samples with the composition $x=0.0$ or 0.1 appear to contain two $n=2$ phases with the same stoichiometry, as

FIG. 1. Ruddlesden–Popper structures: (a) K_2NiF_4 ($n=1$), (b) $\text{Sr}_2\text{LnMn}_2\text{O}_7$ ($n=2$), (c) perovskite ($n=\infty$). MnO_6 octahedra are shaded, hollow circles represent Sr/Ln atoms.

judged by the unit cell volume, but with a different distribution of Sr^{2+} and Nd^{3+} cations over the available sites,¹² whereas $\text{Sr}_{1.8}\text{Nd}_{1.2}\text{Mn}_2\text{O}_7$ can be prepared to contain a single $n=2$ phase, albeit contaminated by $n=\infty$ perovskite.¹³ The difference between the Nd- and La-containing $n=2$ compounds demonstrates that the electronic properties are very sensitive to elemental composition, and diffraction experiments^{12,14,15} have indicated that the sensitivity can be traced to the subtle structural changes which are brought about by the variations in composition. We have previously shown^{16,17} that the introduction of smaller Ln cations (Ho^{3+} , Y^{3+}) into the $n=2$ structure results in the formation of a spin-glass phase at low temperatures, and also in the loss of CMR. In this article, we describe the magnetic behavior of $\text{Sr}_{1.8}\text{La}_{1.2-x}\text{Nd}_x\text{Mn}_2\text{O}_7$, a system which can be thought of as a solid solution between the "conventional" Mn-containing CMR compound $\text{Sr}_{1.8}\text{La}_{1.2}\text{Mn}_2\text{O}_7$ and the "unconventional" $\text{Sr}_{1.8}\text{Nd}_{1.2}\text{Mn}_2\text{O}_7$. We also discuss the pressure dependence of the CMR in $\text{Sr}_{2-x}\text{Nd}_{1+x}\text{Mn}_2\text{O}_7$ and show how the application of pressure can mimic the effect of changes in chemical composition. Finally, we discuss the consequences for the magnetic and magnetotransport properties of introducing the Sm^{3+} cation, intermediate in size between Nd^{3+} and Ho^{3+} , into the $n=2$ structure.

II. EXPERIMENT

The $n=2$ RP system $\text{Sr}_{1.8}\text{La}_{1.2-x}\text{Nd}_x\text{Mn}_2\text{O}_7$ could not be prepared free of perovskite impurity by traditional ceramic techniques. A synthetic strategy which involved the use of a Bi_2O_3 flux¹⁰ was more successful. Stoichiometric quantities of SrCO_3 , Nd_2O_3 , La_2O_3 , and MnO_2 were ground together with a small amount of Bi_2O_3 such that the initial cation composition was $\text{Sr}_{1.8}\text{La}_{1.2-x}\text{Nd}_x\text{Mn}_2\text{Bi}_{0.1}$. The reaction mixture, contained in an alumina crucible, was heated at 900 (12 h) and 1200 °C (12 h) before being pelletized and heated at 1500 °C for a total of 36 h. X-ray powder diffraction measurements, carried out on a Siemens D5000 diffractometer using $\text{Cu K}\alpha_1$ radiation, showed that the products were free of $n=\infty$ and $n=1$ impurity phases. The $\{0\ 0\ 10\}$ reflection of all samples in the composition range $0.1 \leq x \leq 1.1$ had a full width at half maximum (FWHM) of $\Delta 2\theta \sim 0.1^\circ$. We have previously shown^{11,13} that values less than this are characteristic of unstrained, monophasic samples, whereas larger values indicate that the sample either has a high degree of strain or is actually biphasic, possibly in a very subtle way.¹² The quality of the new samples was thus uncertain, and structure refinement by Rietveld profile analysis^{18,19} was carried out in order to determine their true nature. Analysis by ICP emission spectroscopy established that the metal content of the samples was in agreement with

the expected values and iodometric titrations established $y = 7.00(2)$ for the oxygen content in $\text{Sr}_{1.8}\text{La}_{1.2-x}\text{Nd}_x\text{Mn}_2\text{O}_y$. The temperature dependence of the magnetization of three selected samples ($x=0.2, 0.7, 1.1$) was measured in an applied field of 1 kG using a Quantum Design MPMS superconducting quantum interference device (SQUID) magnetometer.

The synthesis of $\text{Sr}_{2-x}\text{Nd}_{1+x}\text{Mn}_2\text{O}_7$ ($x=0.0, 0.1$) has been described previously.⁹ These samples both contain two $n=2$ RP phases, but no $n=\infty$ perovskite was detectable by x-ray or neutron diffraction. The pressure dependence of the resistance of $\text{Sr}_{2-x}\text{Nd}_{1+x}\text{Mn}_2\text{O}_7$ ($x=0.0, 0.1$) was measured using currents $21 \leq I/nA \leq 210$. No current dependence of the resistance was detected. The magnetoresistance was measured using standard, low-frequency (30 Hz), four-wire ac techniques in magnetic fields up to 15 T, with the current perpendicular to the magnetic field. Field reversal verified that the Hall contribution to the magnetoresistance was negligible. The measurements were restricted to (P, T, B) regions where the sample resistance was less than $10^5 \Omega$. They were performed on two different pieces of ceramic sample to verify the sample independence of the observed signal. All resistance values were normalized to the sample resistance at ambient pressure, 275 K and 0 T. A standard piston-cylinder cell with petroleum spirit as pressure medium was used²⁰ to apply pressure at room temperature. The pressure inside the cell, which was monitored with a calibrated manganin wire,²¹ decreased by ~ 0.3 GPa during cooling from room temperature to 4.2 K; all pressures quoted are room temperature values.

A sample of $\text{Sr}_{1.8}\text{Sm}_{1.2}\text{Mn}_2\text{O}_7$ was prepared by firing a stoichiometric mixture of SrCO_3 , Sm_2O_3 , and MnO_2 in air at 800 (24 h), 1000 (24 h), and 1350 °C (10 days). Initial x-ray characterization was carried out using a Siemens D5000 diffractometer, and the sample was then examined under higher resolution using the diffractometer 2.3 at the SRS, Daresbury Laboratory ($\lambda = 1.3997 \text{ \AA}$, $\Delta 2\theta = 0.01^\circ$). The zero field cooled (ZFC) and field cooled (FC) magnetic susceptibility of the sample was measured in a field of 500 G. Ambient pressure magnetoresistance measurements on $\text{Sr}_{1.8}\text{Sm}_{1.2}\text{Mn}_2\text{O}_7$ were accomplished using a four-terminal dc technique in fields of up to 14 T.

III. RESULTS

Analysis of the x-ray diffraction patterns of the compositions $\text{Sr}_{1.8}\text{La}_{1.2-x}\text{Nd}_x\text{Mn}_2\text{O}_7$ showed (Table I) that they all contain more than one $n=2$ RP phase, as do $\text{Sr}_2\text{LaMn}_2\text{O}_7$ and $\text{Sr}_2\text{NdMn}_2\text{O}_7$.^{12,14} The relative proportions of the two phases varied in an irregular manner as a function of x . In the compositions that were selected for further study (x

FIG. 2. Magnetic susceptibility of $\text{Sr}_{1.8}\text{La}_{1.2-x}\text{Nd}_x\text{Mn}_2\text{O}_7$ measured in an applied field of 1 kG for x = (a) 0.2, (b) 0.7, and (c) 1.1.

=0.2, 0.7, 1.1) the phase fractions were 40/60, 53/47, and 97/3; thus the composition $\text{Sr}_{1.8}\text{La}_{0.1}\text{Nd}_{1.1}\text{Mn}_2\text{O}_7$ appeared to be almost monophasic at the resolution of our powder diffraction apparatus. The data gave no indication of (Sr, La, Nd) cation ordering over the two crystallographically distinct sites available—one in the perovskite blocks and the other in the rock-salt layers. As expected, the unit cell volume showed a general decrease as the concentration of the smaller Nd^{3+} cation increased. The magnetic susceptibility, measured in a field of 1 kG, of the three chosen compositions is plotted as a function of temperature in Fig. 2. The composition $x=0.2$ shows a rise in susceptibility below 20 K, but otherwise shows qualitatively similar behavior to $x=0.0$ ⁸ (Fig. 3), with a Curie point apparent at 85 K and a suggestion of short range or two dimensional ordering below 230 K (cf. 126 and 250 K for $x=0.0$). A saturation magnetic moment of $2.23 \mu_B$ per Mn cation was measured in a field of 1 kG. The Curie point is not visible in the data collected on $x=0.7$, and the susceptibility of $x=1.1$ is very similar to that of the composition $x=1.2$, although the marked rise in the magnetization occurs at 290 K (270 K) in the former (latter); neu-

FIG. 3. Magnetic susceptibility of $\text{Sr}_{1.8}\text{La}_{1.2-x}\text{Nd}_x\text{Mn}_2\text{O}_7$ measured in 100 G for $x=0.0$ and 0.2.

tron diffraction experiments have previously failed to detect any long-range magnetic order in $\text{Sr}_{1.8}\text{Nd}_{1.2}\text{Mn}_2\text{O}_7$.¹³

The normalized resistance of $\text{Sr}_2\text{NdMn}_2\text{O}_7$ between 50 and 300 K is shown in Fig. 4 as a function of pressure and applied field. The zero-field resistance is seen to increase by over three orders of magnitude between room temperature and 80 K. Neither the absolute value nor the temperature dependence of the zero-field resistance are affected significantly by the application of pressure. The temperature dependence of the zero-field resistance under pressure for $170 \leq T/K \leq 300$ can be fitted as an activated process, $\rho = \rho_0 e^{(E/kT)}$, with an activation energy of 110 ± 5 meV, independent of the applied pressure. This implies that the activa-

FIG. 4. Normalized resistance of $\text{Sr}_2\text{NdMn}_2\text{O}_7$ for $50 \leq T/K \leq 300$ at different magnetic fields and (a) ambient pressure, (b) 0.9, and (c) 1.5 GPa.

FIG. 5. (a) Normalized resistance of $\text{Sr}_2\text{NdMn}_2\text{O}_7$ at 1.8 GPa for different magnetic fields. (b) Normalized resistance of $\text{Sr}_{1.9}\text{Nd}_{1.1}\text{Mn}_2\text{O}_7$ at ambient pressure for comparison purposes.

tion energy of this system cannot depend sensitively on the unit cell dimensions. This is a surprising result, particularly in view of the decrease in activation energy observed when $n=\infty$ perovskites are subjected to pressure.^{22,23} The magnetoresistance, however, is strongly dependent on the pressure applied, as illustrated in Fig. 4. Even at temperatures as high as 100 K, the magnetoresistance ratio at 12 T, $(\rho_B - \rho_0)/\rho_B$, changes from $\sim -90\%$ at 0 GPa to $\sim -200\%$ at 1.5 GPa, and there is a marked similarity between the behavior of $\text{Sr}_2\text{NdMn}_2\text{O}_7$ under pressure and $\text{Sr}_{1.9}\text{Nd}_{1.1}\text{Mn}_2\text{O}_7$ at ambient pressure.⁹ This becomes particularly noticeable (Fig. 5) at pressures in excess of 1.5 GPa and in high magnetic fields ($B > 12$ T). In this regime, $\text{Sr}_2\text{NdMn}_2\text{O}_7$ develops a local resistivity maximum at ~ 70 K, similar to that observed in $\text{Sr}_{1.9}\text{Nd}_{1.1}\text{Mn}_2\text{O}_7$ at high fields and ambient pressure [Fig. 5(b)]. It is interesting to note that once this maximum has developed, its position and height are almost pressure independent. This could be an indication that the maximum is due to the completion of a pressure-field assisted ordering process among the Mn spins.

The x-ray diffraction data collected on $\text{Sr}_{1.8}\text{Sm}_{1.2}\text{Mn}_2\text{O}_7$ using a laboratory-based diffractometer indicated that we had been successful in preparing a monophasic, tetragonal $n=2$ RP sample, despite the fact that our previous attempts to prepare $\text{Sr}_2\text{SmMn}_2\text{O}_7$ had resulted in the formation of two $n=2$ phases with similar but different structural characteristics.²⁴ However, close scrutiny of the high resolution data collected at the synchrotron radiation source showed that the new sample was contaminated with

 $\text{Mn}-\text{O}(1)=1.965(2)$, $\text{Mn}-\text{O}(2)=2.06(1)$, $\text{Mn}-\text{O}(3)=1.912 59(4)$,
 $\text{Mn}(z)-\text{Mn}(-z)=3.931(5)$ \AA .

~ 2.8 wt % of a perovskite ($n=\infty$) phase. The unit cell parameters refined to the following values: for $n=2$, $a=3.825 13(2)$, $c=20.1269(1)$ \AA ; for $n=\infty$, $a=5.4205(5)$, $b=7.6840(6)$, $c=5.4130(5)$ \AA . The Sr^{2+} and Sm^{3+} cations order in the $n=2$ phase such that 84% of the smaller Sm^{3+} cations are nine coordinate in the rock-salt layer [$\text{Sr}/\text{Sm}(2)$], with the majority of the Sr^{2+} cations being twelve coordinate within the perovskite blocks [$\text{Sr}/\text{Sm}(1)$]. The refined values of the atomic coordinates are presented in Table II, along with the most important bond lengths; note that O(1) lies at the center of the perovskite block, the bond $\text{Mn}-\text{O}(2)$ is directed along z into the rock-salt layer, and $\text{Mn}-\text{O}(3)$ lies within the xy sheets; we have used the same labeling scheme previously.^{12,14} Although it is not ideal to determine these parameters by x-ray diffraction, the high absorption cross section of Sm renders a neutron diffraction study impractical. The magnetization of $\text{Sr}_{1.8}\text{Sm}_{1.2}\text{Mn}_2\text{O}_7$ is plotted as a function of temperature in Fig. 6. There is a sharp rise at 140 K, and some hysteresis is apparent below this temperature; a maximum is observed at ~ 35 K. A weak magnetization of $\sim 0.06 \mu_B$ per formula unit is seen at 5 K. The resistivity is plotted as a function of temperature and magnetic field in Fig. 7. The smooth curves are characteristic of an insulator, and no phase transition is apparent at 140 K. The magnetoresistance $[(\rho_B - \rho_0)/\rho_0] \times 100\%$ apparently increases throughout the measured temperature range and reaches a maximum value of $\sim -10\%$.

IV. DISCUSSION

The data described above suggest that it is possible to dope $\text{Sr}_{1.8}\text{La}_{1.2}\text{Mn}_2\text{O}_7$ with Nd, thereby weakening the strength of the interactions producing long-range ferromagnetic ordering. Previous structural studies^{13,15} suggest that this is likely to involve a lengthening of the Mn–O(2) distance, which will decrease the coupling between neighboring perovskite blocks and reduce the three-dimensional nature of the magnetic interactions. It is interesting to note that the change from one type of magnetic behavior to another occurs gradually with changing composition. As the Nd-content increases, the susceptibility begins to resemble that of $\text{Sr}_{1.8}\text{Nd}_{1.2}\text{Mn}_2\text{O}_7$, which does not show long-range magnetic ordering.¹³ However, this neat description is too simplistic because it does not take into account the fact that our x-ray data show that the samples are biphasic, and without a more detailed neutron diffraction study we cannot confidently describe the differences in crystal structure and composition between the two phases, and we therefore cannot account fully for the weakening of the ferromagnetic interactions and the generally complex susceptibility behavior shown in Fig. 2. It is likely, for example, that the ferromagnetic transition and the low temperature rise in susceptibility seen for $x = 0.2$ in Fig. 2(a) are attributable to the two different components of the sample. Nevertheless, Nd-doping clearly influences the magnetic properties of this system, and our data give reason to believe that, for relatively low, but as yet badly defined ($x < 0.7$), levels of Nd doping it may be possible to tune T_c in this system chemically by controlling the

elemental distribution over the A sites within either the perovskite blocks or the rock-salt layers. This implies that it will also be possible to tune the temperature of maximum magnetoresistance, but more magnetotransport measurements are needed to prove this point. The suggestion that the properties can be controlled by the La/Nd ratio should sound a warning to those who treat these compounds as a Mn–O network with benign lanthanide cations playing only a space-filling role in the structure.

The results of our high pressure experiments suggest that the application of hydrostatic pressure to $\text{Sr}_2\text{NdMn}_2\text{O}_7$ has a similar effect, with regard to CMR, to increasing the Nd:Sr ratio. At ambient pressure, increasing the Nd content produces a contraction of the unit cell parameter a , but an increase in c , and, given that pressure and increasing Nd content have the same effect on CMR and that pressure will decrease both unit cell parameters, it is reasonable to assume that the change in a is of greater significance. Our samples of both $\text{Sr}_2\text{NdMn}_2\text{O}_7$ and $\text{Sr}_{1.9}\text{Nd}_{1.1}\text{Mn}_2\text{O}_7$ are biphasic, and we have described them as containing both an antiferromagnetic phase and a spin-glass phase, with the spin-glass fraction being more significant in the Nd-rich sample. The occurrence of the latter phase was attributed to frustration caused by the presence of both ferromagnetic and antiferromagnetic interactions. Furthermore, the lower ordered magnetic moment per Mn cation and the lower Néel temperature of $\text{Sr}_{1.9}\text{Nd}_{1.1}\text{Mn}_2\text{O}_7$ indicate that frustration-induced magnetic disorder is relatively large even in the magnetically ordered component of the Nd-rich sample. Our new results can then be taken to suggest that pressure produces an increase in the degree of frustration in antiferromagnetic $\text{Sr}_2\text{NdMn}_2\text{O}_7$ by enhancing the relative strength of any ferromagnetic interactions in the ordered phase. This is consistent with the magnetic structure¹² which consists of ferromagnetic sheets perpendicular to z ; the decrease in a will increase the strength of the ferromagnetic coupling and hence increase the degree of frustration in the antiferromagnetic structure. Susceptibility or neutron measurements under pressure are necessary to test this proposal further.

Finally, our data on $\text{Sr}_{1.8}\text{Sm}_{1.2}\text{Mn}_2\text{O}_7$ demonstrate the need for careful diffraction studies in order to identify the phases present in manganate samples. Damay *et al.*²⁵ have reported that perovskite compositions $\text{Sm}_{1-x}\text{Sr}_x\text{MnO}_3$ show a Curie temperature at ~ 140 K, with a saturation moment per Mn cation of $\sim 1 \mu_B$ for $x = 0.44$ in a field of 500 G. Thus the magnetization of our sample can be attributed to the presence of 3% of the perovskite $\text{Sm}_{0.56}\text{Sr}_{0.44}\text{MnO}_3$, essentially the fraction estimated from our x-ray study. This would not have been observed had we relied on our laboratory-based powder diffractometer, although it is a relatively modern, high-resolution machine. Indeed, the presence of this phase was not taken into account in our discussion of magnetic data collected before high resolution x-ray studies had been performed,¹⁶ and our earlier discussion is therefore flawed. The perovskite phase dominates the magnetization data, but it is present at too low a concentration to influence the magnetotransport data, as can be seen from a comparison of our data with those of Damay *et al.*, which show a metal-insulator transition. We can conclude that the majority, n

$n=2$ phase does not show magnetoresistance on the scale of the La and Nd analogs, even though we cannot describe the temperature dependence of the susceptibility. As in $\text{Sr}_2\text{HoMn}_2\text{O}_7$, the preferential occupation of the perovskite block site by the larger Sr^{2+} cation results in a large Mn–Mn distance (3.931 Å) along z within a double layer, and this is likely to weaken the interatomic interactions along the axis in comparison to those within the xy plane; it is also likely to prevent the exchangestriction which stabilizes the antiferromagnetic phase in $\text{Sr}_2\text{NdMn}_2\text{O}_7$. Although we cannot draw any firm conclusions about the magnetic properties of the $n=2$ phase from our susceptibility data, the similarity between the structural data described above and those reported previously for $\text{Sr}_2\text{HoMn}_2\text{O}_7$ and $\text{Sr}_2\text{YMn}_2\text{O}_7$ ¹⁷ leads us to predict spin glass behavior at low temperatures (<50 K) in $n=2$ $\text{Sr}_{1.8}\text{Sm}_{1.2}\text{Mn}_2\text{O}_7$. It is possible that the susceptibility maximum at 35 K (Fig. 6) corresponds to the glass transition temperature. It should be noted that the Ho- and Y-containing compounds show a slight distortion from the ideal RP structure. This involves oxide ion displacements arising from the rotation of MnO_6 octahedra, and is easily detected in neutron diffraction experiments. However, we would not expect to have detected it in our x-ray experiments on the Sm compound.

Finally, we wish to emphasise that, having attempted to prepare a number of $n=2$ RP phases, and having paid careful attention to synthesis conditions, we have never succeeded in preparing a monophasic material. We have prepared samples free of $n=\infty$ perovskite, but they have always contained two $n=2$ phases, for example $\text{Sr}_2\text{NdMn}_2\text{O}_7$. We have made highly crystalline $n=2$ phases, but they have always been contaminated by perovskite, for example $\text{Sr}_{1.8}\text{Sm}_{1.2}\text{Mn}_2\text{O}_7$ as described above. Furthermore, even samples which appear to contain only one $n=2$ phase show a relatively high concentration of intergrowths of other RP phases.²⁶ Our final conclusion is thus that any attempt to make an unambiguous interpretation of the physical properties of these materials is fraught with difficulty. The problems may diminish if single crystals become available, but they are unlikely to disappear altogether.

Role of intergrowths in the properties of naturally layered manganite single crystals (invited)

S. D. Bader,^{a)} R. M. Osgood III, D. J. Miller, J. F. Mitchell, and J. S. Jiang
Materials Science Division, Argonne National Laboratory, Argonne, Illinois 60439

Two-layered Ruddlesden–Popper phase $\text{SrO}(\text{La}_{1-x}\text{Sr}_x\text{MnO}_3)_2$, with $x=0.3$ and 0.4 , exhibits colossal magnetoresistance, a magnetic anisotropy which is strongly composition-dependent, very little remanence, and an anomalous low-field magnetization (M) plateau between the Curie temperature (T_C) and $T^* \sim 300$ K. The resistivity peaks near T_C for both in-plane and out-of-plane currents. The magnetization plateau is not intrinsic to the crystal, but is attributed to intergrowth defects, consisting of one additional or missing SrO blocking layers, as observed in transmission electron micrographs. The intergrowths exhibit interesting two-dimensional magnetic behavior, for both the $x=0.3$ and 0.4 compositions. For $x=0.4$, M scales as $(1-T/T^*)^\beta$, with $\beta=0.25 \pm 0.02$. For $x=0.3$, the intergrowths exhibit an easy axis in the a - b plane due to the shape anisotropy, while for $T < T_C$, M lies along the c axis. © 1998 American Institute of Physics. [S0021-8979(98)43311-5]

I. INTRODUCTION

Manganites, based on the perovskite structure type, are a fascinating class of materials, exhibiting both the colossal magnetoresistance (CMR) phenomenon¹ and a host of interesting magnetic properties.^{2,3} Recently, Moritomo *et al.* fabricated these materials in the two-layered form;² i.e., the $n=2$ variant of the Ruddlesden–Popper series $(\text{La}, \text{Sr})_{n+1}\text{Mn}_n\text{O}_{3n+1}$, and there have been a number of subsequent investigations of this material.^{3–9} Figure 1 illustrates the $n=1, 2, \infty$ members of this family. The unit cell may be written: $\text{SrO}(\text{La}_{1-x}\text{Sr}_x\text{MnO}_3)_2$, where it is clear that two MnO_6 octahedra are separated from one another by an insulating layer of SrO . The structure is tetragonal, with the a - b plane parallel to the layers of MnO_6 and the c axis perpendicular.³ The $n=2$ variant of this family was found to have a $\sim 20\,000\%$ CMR at 129 K with $H=7$ T, while at low fields (0.3 T), a CMR of $\sim 200\%$ was found (at 129 K).² These materials (including the $n=\infty$ variety) exhibit a competition between antiferromagnetism due to superexchange, and ferromagnetism due to double exchange. For $x=0$, the material is antiferromagnetic, while in the region $x \approx 0.2$ – 0.4 , the materials are ferromagnetic and exhibit a metal–insulator transition at T_C . T_C moves appreciably in an external field H , which in turn shifts and broadens the metal–insulator transition and causes CMR. An external field is thought to align the Mn sites and therefore allow the electron (via the double exchange mechanism) to delocalize and “hop” between the Mn sites.

As in the cuprate superconductors,¹⁰ not all of the interesting physics for the manganites is confined in the temperature region $T < T_C$. Several studies have reported short-range magnetic order for $T > T_C$ in these layered materials (both $x=0.3$ and 0.4).^{3,4,11,12} One naturally asks the question: “to what extent is this magnetic order intrinsic to the layered structure of the material?” We find that the CMR occurs at low fields at $T=T_C$ for the current both in the a - b plane and

along the c axis. The high temperature magnetization is, however, interesting in its own right; it is attributed to intergrowth defects extrinsic to the crystal, which exhibits novel, two-dimensional magnetic behavior.

II. EXPERIMENT

Crystals of $\text{La}_{2-2x}\text{Sr}_{1+2x}\text{Mn}_2\text{O}_7$ ($x=0.3, 0.4$) were grown from polycrystalline rods of the same nominal composition using the traveling-floating-zone technique in an optical image furnace (NEC model SC-M15HD). The precursor rods were prepared by solid-state synthesis from high purity ($>99.99\%$) starting materials: La_2O_3 (prefired in flowing O_2 at 1000°C for 12 h), MnO_2 , and SrCO_3 . After several firings at 1000 – 1350°C , the powders were isostatically pressed into rods suitable for zone melting. The growth atmosphere was 20% O_2 for $x=0.3$ and 0.4 . In each case, the crystals grew with the c axis normal to the zone travel direction. The resulting highly textured polycrystalline boules can be cleaved readily to yield shiny black crystals of layered manganite. Typical dimensions of the cleaved crystals are $2 \times 2 \times 0.1$ mm³. Back-reflection x-ray Laue photographs establish that in all cases the cleaved crystals have the c axis oriented normal to the thin plates. Magnetization and suscep-

FIG. 1. Diagram of the structure $\text{SrO}(\text{La}_{1-x}\text{Sr}_x\text{MnO}_3)_2$, reproduced from Ref. 2. The variable n refers to the number of MnO_6 octahedra layers in the bilayer. The shaded atoms are the La, Sr cations, the white atoms are O, and the black atom in the center of the O_6 octahedron is the Mn atom.

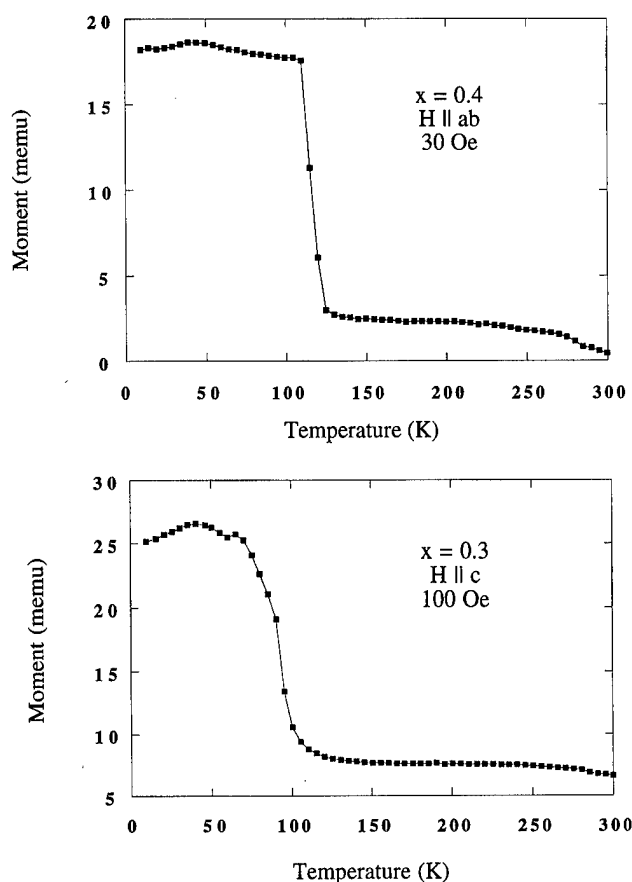

FIG. 2. Magnetic moment vs temperature for (a) $x=0.4$ ($H=30$ Oe $\parallel ab$); (b) $x=0.3$ ($H=50$ Oe $\parallel c$).

tibility (χ) measurements were made on both a superconducting-quantum interference device (SQUID) and an extraction magnetometer from Quantum Design, equipped with a 7 and 9 T superconducting solenoid, respectively. The trapped flux in the solenoid (~ 10 Oe) was monitored, so that the field values given are correct to within ± 0.5 Oe. Measurements were made with the applied field both parallel to the a - b plane ($H \parallel ab$) and parallel to the c axis ($H \parallel c$). Resistivity measurements were made on thin platelets obtained by crushing the boule; leads were connected by attaching Cu wires to sputtered Au contacts. Another platelet from the same boule was ion-milled and used for transmission electron microscope (TEM) measurements.

III. MAGNETIZATION AND TRANSPORT

Figure 2(a) displays M vs T ($H=30$ Oe $\parallel ab$) for $x=0.4$; Figure 2(b) illustrates M vs T ($H=100$ Oe $\parallel ab$) for $x=0.3$. For both compositions, there are two plateaux below the two transitions. The lower transition is T_C (~ 94 K for $x=0.3$ and 116 K for $x=0.4$); the upper transition is at $T=T^* \sim 300$ K. In Fig. 2b, T^* is not as visible for the $x=0.3$ sample as it is for $x=0.4$ because of the higher field employed for this measurement (100 Oe), which tends to smear out the transition. A measurement of M vs T with $H=15$ Oe near T^* is displayed in Fig. 3. Measurements of M vs H below T_C yield a ferromagnetic hysteresis loop, albeit one with virtually no remanence [see Fig. 4(a) for $H \parallel ab$ and

FIG. 3. Magnetic moment vs temperature for $x=0.3$ ($H=15$ Oe $\parallel ab$, $T \approx T^*$). Three transitions are identified.

$H \parallel c$ in $x=0.4$; see Fig. 4(b) for $H \parallel ab$ and $H \parallel c$ in $x=0.3$, all at 5 K]. The easy axis, determined by the saturation field, lies in the a - b plane for $x=0.4$ and along c for $x=0.3$, in agreement with Ref. 3. Measurements of M vs H for $T_C < T < T^*$ yield a small ferromagnetic loop superimposed on a

FIG. 4. Magnetization (normalized to the saturation magnetization M_s) vs H for (a) $x=0.4$, (b) $x=0.3$ ($H \parallel ab$: filled symbols, $H \parallel c$: clear symbols, $T=5$ K for both compositions). Measurements were made sweeping H from negative to positive values and back to $M=0$.

FIG. 5. (a) Magnetic moment vs applied field (H) at 250 K for $H||ab$ (filled symbols) and $H||c$ (clear symbols). Both measurements are superimposed on a linear paramagnetic background from the intrinsic portion of the crystal, which is displayed in (b) for $H||ab$. Two lines in (b) indicate the kink near $H=0$ which is due to the ferromagnetic response of the extrinsic material. All measurements in this figure are from the same sample.

paramagnetic background, in agreement with neutron diffraction experiments, which have been able to sense moments only for $T < T_C$.⁵ The high-temperature paramagnetism therefore must represent short range order. Figure 5(a) displays M vs $H||ab$ and M vs $H||c$ in $x=0.3$, while Fig. 5(b) displays the M vs $H||ab$ data on a larger scale; the ferromagnetic part of the signal manifests itself here as a kink near $H=0$. These measurements are all from the same sample. Note the scales on Figs. 5(a) and 5(b); the ferromagnetic signal is masked by the paramagnetic signal from the intrinsic material.

Associated with the T_C illustrated in Fig. 2 for $x=0.3$ are peaks in the resistivity ρ and in the CMR, displayed in Fig. 6 for two different directions of the current j . There was a slight difference in $T_C \approx 90$ K between the two separate samples measured in Fig. 6; this difference has been normalized out. Note that the resistance was much higher along the c axis, in agreement with Ref. 3. Note that peaks for both ρ_{ab} and ρ_c at $H=0$ are at $T \approx T_C$. The authors of Ref. 3 observed a large peak in ρ_{ab} , the resistivity measured in the $a-b$ plane, for $T > T_C$. This was considered a sign of ferromagnetic correlations within the MnO_6 planes and lack of correlation between the planes. Below T_C , where M lies

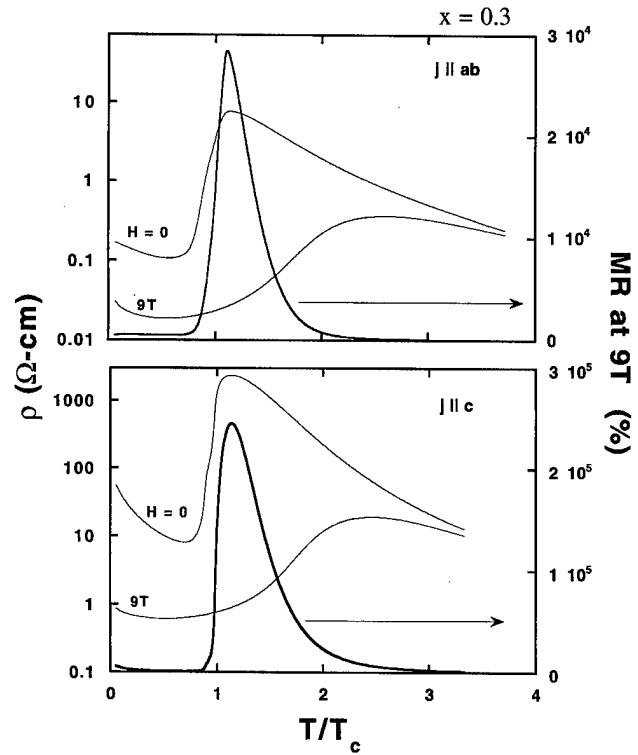

FIG. 6. Measurement of resistivity vs applied field for (a) $j||ab$ and (b) $j||c$ for the $x=0.3$ composition. Measurements were made on separate samples, both of whom had $T_C \approx 90$ K; the minor difference between the T_C 's has been normalized out.

only along c , Kimura *et al.* rationalized the drop in ρ_{ab} they observed as being due to the disappearance of spin disorder in the $a-b$ plane.³ We did not observe such a peak in ρ_{ab} for $T > T_C$ for $x=0.3$. We conclude that the high-temperature magnetism is an extrinsic phenomenon, due to an intergrowth phase, which was presumably also present in the similarly prepared samples used in Ref. 3.

FIG. 7. High-resolution TEM micrograph showing one intergrowth (marked with a pointer) with $n=5$ for the $x=0.4$ composition.

FIG. 8. High-resolution TEM micrograph showing two intergrowths (marked with a pointer) with $n=1$ for the $x=0.4$ composition.

IV. INTERGROWTHS

Seshadri *et al.* have demonstrated the presence of intergrowths in these materials, using TEM.⁷ Intergrowths can be due to missing or extra layers of SrO atoms between the MnO_6 octahedra. Such defects represent $n \neq 2$ variants of the Ruddlesden–Popper series. Figures 7 and 8 display high-resolution TEM images from samples with $x=0.4$. The insulating double SrO layer is the white band. In Fig. 7, the regular series of white bands is interrupted by a $n=5$ intergrowth; in Fig. 8, an extra white band divides two $n=1$ intergrowths. Such intergrowths are also observed in the $x=0.3$ samples (see Fig. 9). An estimate of the intergrowth volume fraction can be made by dividing the height of the hysteresis loop measured at 250 K by the saturation magnetic moment (measured with H large enough to saturate M at $T < T_C$). We obtain a volume fraction of $\sim 0.1\%$ intergrowths in the $x=0.4$ samples and $\sim 0.6\%$ intergrowths in the x

$=0.3$ samples, although there was a variation of $\pm 0.3\%$ among samples with $x=0.3$ (four with this composition were measured).

Potter *et al.*⁴ have given evidence that the magnetism of the intergrowths is two dimensional. For $T \approx T^*$, M scales as $(1 - T/T^*)^\beta$, where $\beta = 0.25 \pm 0.02$ for the $x=0.4$ composition, which is reminiscent of two-dimensional (2D) behavior. For the $x=0.3$ composition, three transitions in the M vs T data are observed, as displayed in Fig. 3, indicating the presence of three different distributions of intergrowths. It was therefore not possible to obtain an exponent for $x=0.3$.

Another experimental observation that strongly supports the influence of the intergrowths above T_C is the fact that hysteresis loops measured with the field along the c axis are much harder than those measured with the field in the a - b plane [see Fig. 5(a)]. This is consistent with the picture of two-dimensional intergrowths running parallel to the a - b plane. Such inclusions are magnetically hard along the c axis, due to shape anisotropy, in contrast with the easy axis anisotropy along the c axis observed below T_C for the intrinsic material. Were the magnetic signal above T_C to be due to intralayer correlations only (the model proposed in Ref. 3), there would not necessarily be an anisotropy in the magnetization loops.

V. CONCLUSIONS

The two-layered Ruddlesden–Popper phase $\text{SrO}(\text{La}_{1-x}\text{Sr}_x\text{MnO}_3)_2$, with $x=0.3$ and 0.4 , exhibits CMR at T_C at low H and a magnetic anisotropy which is strongly composition-dependent. The magnetic order observed for $T > T_C$ includes not only the short-range order response of the intrinsic material, but a minor ferromagnetic signal evident at low fields due to intergrowths. These intergrowths are clearly visible in TEM images and exhibit novel two-dimensional magnetism. The intergrowths are magnetically hard along the c axis in the $x=0.3$ material, despite the fact that the c axis is easy for this composition. We find that the $x=0.3$ and

FIG. 9. Bright-field micrograph of the $x=0.3$ composition showing (a) perfect crystal, (b) crystal with intergrowths. In (b) the intergrowths are visible as vertical streaks in the photograph running parallel to the a - b plane.

0.4 compositions differ strongly only in the magnetic anisotropy of the intrinsic material, not in the temperature dependence of the resistivity or magnetization.

The magnetic properties and the microstructure of Nd-Fe-B and Nd-Fe-Co-Ga-B die upset magnets produced from amorphous materials were studied. The Nd-Fe-B die upset magnets had fine polygonal Nd₂Fe₁₄B grains and showed magnetic anisotropy. The compositional modification and optimization of the die upset condition led to the increase in the remanence and coercivity values of the Nd-Fe-B die upset magnets. The optimally deformed Nd-Fe-Co-Ga-B die upset magnets showed the maximum energy product of 54.4 MGOe. © 1998 American Institute of Physics. [S0021-8979(98)15011-9]

INTRODUCTION

The maximum energy products of Nd-Fe-B magnets, which are usually produced by sintering and melt-spinning,^{1,2} are dependent on the degree of the crystallographic alignment of the Nd₂Fe₁₄B phase. In the sintered magnets, alignment of the Nd₂Fe₁₄B phase is achieved by the prior green compaction of the crushed ingot powders in an applied magnetic field.¹ Nd-Pr-Dy-Fe-B sintered magnets with the highest maximum energy product of 54.2 MGOe have been reported.³ On the other hand, alignment of the Nd₂Fe₁₄B phase is achieved by die upsetting in the melt-spinning approach.⁴ Amorphous melt-spun ribbons are comminuted and then are consolidated into bulk form by hot pressing before die upsetting. Although as-hot-pressed magnets have randomly oriented Nd₂Fe₁₄B grains, subsequent die upsetting gives rise to the crystallographic alignment of the Nd₂Fe₁₄B phase.^{5,6} Even though the die upset magnets have some advantages such as the finer Nd₂Fe₁₄B grains and lower oxygen content than the sintered counterparts, the maximum energy product of the die upset magnets are not yet comparable to those of the sintered counterparts. The optimization of the processing will lead to further improvement of the crystallographic alignment of the Nd₂Fe₁₄B phase in the die upset magnets, thereby enhancing the maximum energy product.

In the die upset magnets, the inhomogeneity of the as-hot-pressed magnets deteriorates the crystallographic alignment of the Nd₂Fe₁₄B phase during the die upsetting.⁷ It has been reported that the Nd-Fe-B die upset magnets produced from the amorphous materials with the homogeneous micro-

structure exhibit the higher maximum energy products than those produced from the as-hot-pressed magnets.⁸ In this study, we are trying to improve the maximum energy products of the die upset magnets produced from the amorphous materials by optimizing the composition and the processing conditions. The magnetic properties and the crystallographic alignment of the die upset magnets produced from the amorphous materials are compared to those of the die upset magnets produced from the as-hot-pressed magnets.

EXPERIMENT

Nd_{13.5}Fe_{80.5}B₆, Nd_{13.5}(Fe_{0.975}Co_{0.025})_{80.5}B₆, and Nd_{13.5}(Fe_{0.975}Co_{0.025})₈₀Ga_{0.5}B₆ alloy ingots were melt-spun in argon onto a copper substrate rotating at a surface velocity of 52 m s⁻¹. The melt-spun ribbons were comminuted and filled into a steel container. The powders were dynamically compacted at a shock pressure of 21 GPa by the impact of a flyer launched by a 25 mm propellant gun. The propellant gun facilities and process have been described in detail elsewhere.⁹ The consolidated powders were taken out from the container by lathing. Typical dimensions of the bulk materials were 20 mm thick and 25 mm in diameter. For comparison, the melt-spun ribbons were consolidated into bulk form by hot pressing. The bulk materials and the as-hot-pressed materials were deformed by die upsetting at a reduction rate of about 5 × 10⁻² mm s⁻¹. The thicknesses of the specimens were successfully reduced from 20 to 4 mm at temperatures between 963 and 1073 K in an argon atmosphere.

The specimens were examined by x-ray diffraction (XRD) using Cu K_α radiation. The microstructures of the specimens were examined under a transmission electron mi-

croscope (TEM). In the die upset specimen, the cross-sectional microstructures parallel to the die upset direction were investigated. The magnetic properties of the specimens were determined by a recording fluxmeter with a maximum applied field of 25 kOe after premagnetization in a field of 150 kOe.

RESULTS AND DISCUSSION

Figure 1 shows the XRD patterns of the bulk materials of the $\text{Nd}_{13.5}\text{Fe}_{80.5}\text{B}_6$ alloy and those die upset at 1023 K. The XRD pattern of the bulk materials shows only a fairly broad peak at around 40° , which is a characteristic of an amorphous structure. This indicates that the bulk material produced from the melt-spun ribbons maintains the amorphous state. On the other hand, the XRD pattern of the die upset specimen is well indexed according to the tetragonal $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase. This suggests that the heat exposure during the die upsetting of the amorphous bulk materials results in the crystallization of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase as is the case for the die upsetting of the as-hot-pressed magnets.^{4,6}

Figure 2 shows the TEM micrographs of the bulk materials of the $\text{Nd}_{13.5}\text{Fe}_{80.5}\text{B}_6$ alloy and those die upset at 1023 K. The microstructure of the bulk material is featureless, and the corresponding selected area diffraction (SAD) pattern of the specimen shows a diffuse halo. This suggests that the bulk material consists of the amorphous phase. In the die upset specimen, the polygonal crystallites with an average

FIG. 2. TEM micrographs of (a) bulk materials of $\text{Nd}_{13.5}\text{Fe}_{80.5}\text{B}_6$ alloy and (b) those die upset at 1023 K.

FIG. 3. Demagnetization curves of (a) bulk materials of $\text{Nd}_{13.5}\text{Fe}_{80.5}\text{B}_6$ alloy and those die upset at 1023 K. The die upset specimens were measured in the (b) parallel and (c) normal to the die upset direction.

diameter of about $0.1 \mu\text{m}$ are seen in the microstructure. This indicates that the die upset magnets produced from the amorphous bulk materials consists of fine $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains with the polygonal shape.

Figure 3 shows the demagnetization curves of the bulk materials of the $\text{Nd}_{13.5}\text{Fe}_{80.5}\text{B}_6$ alloy and those die upset at 1023 K. The coercivity of the bulk material remains as low as that of amorphous melt-spun ribbons. The die upset specimen shows the high coercivity value. This is due to the fine $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains of the die upset magnets. The anisotropy of the die upset magnets is characterized by the significantly higher remanence in the parallel direction than in the normal direction. The $\text{Nd}_{13.5}\text{Fe}_{80.5}\text{B}_6$ die upset magnets show a maximum energy product of 47.7 MGOe with an intrinsic coercivity of 7.3 kOe. The increase in the coercivity value of $\text{Nd}_{13.5}\text{Fe}_{80.5}\text{B}_6$ die upset magnets would give the magnets with the excellent high maximum energy products.

Figure 4 shows the dependence of the maximum energy product of the die upset magnets on the die upset temperature. The substitution of Co or Ga for Fe of the $\text{Nd}_{13.5}\text{Fe}_{80.5}\text{B}_6$ alloy results in the increase of the optimal die upset temperature to obtain the high maximum energy prod-

FIG. 4. Dependence of the maximum energy product, $(BH)_{\text{max}}$, of the die upset magnets on the die upset temperature.

FIG. 5. XRD patterns of $\text{Nd}_{13.5}(\text{Fe}_{0.975}\text{Co}_{0.025})_{80}\text{Ga}_{0.5}\text{B}_6$ die upset magnets produced from (a) amorphous bulk materials and (b) as-hot-pressed magnets.

ucts. The TEM studies revealed that the resultant die upset magnets consisted of the polygonal $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains as fine as the $\text{Nd}_{13.5}\text{Fe}_{80.5}\text{B}_6$ die upset magnets. The substitution of Co or Ga for Fe of the $\text{Nd}_{13.5}\text{Fe}_{80.5}\text{B}_6$ die upset magnets led to the improvement of the coercivity and the maximum energy products of the Nd-Fe-B die upset magnets as is the case for the die upset magnets produced from the as-hot-pressed magnets.⁶ The resultant $\text{Nd}_{13.5}(\text{Fe}_{0.975}\text{Co}_{0.025})_{80}\text{Ga}_{0.5}\text{B}_6$ die upset magnets exhibit a maximum energy product of 54.4 MGOe with an intrinsic coercivity of 12.5 kOe.

The XRD patterns of the $\text{Nd}_{13.5}(\text{Fe}_{0.975}\text{Co}_{0.025})_{80}\text{Ga}_{0.5}\text{B}_6$ die upset magnets produced from the amorphous bulk materials and the as-hot-pressed magnets are shown in Fig. 5. The polished surfaces of the die upset specimens were examined. Even though both XRD patterns show the pronounced *c*-axis alignment of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase, which is characterized by the prominent (004) and (006) peaks, the die upset magnets produced from the amorphous bulk materials have the higher ratio of the (006) to (105) peaks than those produced from the as-hot-pressed magnets. This indicates that the die upset magnets produced from the amorphous bulk materials have the higher crystallographic alignment of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase than those produced from the as-hot-pressed magnets, which are characterized with the platelike $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains.⁵

The demagnetization curves of these die upset magnets are shown in Fig. 6. The $\text{Nd}_{13.5}(\text{Fe}_{0.975}\text{Co}_{0.025})_{80}\text{Ga}_{0.5}\text{B}_6$ die upset magnets produced from the as-hot-pressed magnets show a maximum energy product of 50.2 MGOe with an intrinsic coercivity of 13.2 kOe. This value is almost comparable to that of the best die upset magnets.¹⁰ The observed higher remanence value of the die upset magnets produced

FIG. 6. Demagnetization curves of $\text{Nd}_{13.5}(\text{Fe}_{0.975}\text{Co}_{0.025})_{80}\text{Ga}_{0.5}\text{B}_6$ die upset magnets produced from (a) amorphous bulk materials and (b) as-hot-pressed magnets.

from the amorphous bulk materials is due to the higher crystallographic alignment of the polygonal $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains. The detailed TEM studies revealed that the die upset magnets produced from the as-hot-pressed magnets contained similar polygonal $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains together with the typical platelet shaped grains.¹¹ Therefore, the further optimization of the hot pressing and die upsetting conditions would lead to an increase in the maximum energy product of the die upset magnets produced from the as-hot-pressed magnets.

The die upset of hot pressed NdFeB magnets modifies the equiaxed grains to platelets, develops the *c*-axis texture parallel to press direction, and improves magnetic properties. The mechanism of *c*-axis alignment has been suggested to be a combination of grain-boundary sliding and anisotropic grain growth in a direction normal to the applied stress. To clearly understand the role of deformation process in grain-boundary sliding or anisotropic grain growth simulations of the die-upset process were performed using ANATARES, a three-dimensional finite element method based deformation modeling software. The stresses and strains in the different regions of a cylindrical Nd-Fe-B magnet at different stages of the die-upset process were determined. The average value of the maximum principal stress (parallel to the upset direction) and total effective strain increased as the upset increased from 50% to 70%. The maximum principal stress and total effective strain show a maximum at the center and decrease in both the thickness and the radial direction due to friction at the die-wall/magnet interface. The stress and effective strain uniformity improves with increase in upset. The data agree well with the variations of texture in the magnet observed using pole figure measurements in this study and texture studies using a synchrotron source. © 1998 American Institute of Physics. [S0021-8979(98)16511-8]

I. INTRODUCTION

The magnequench process for the production of Nd-Fe-B-based magnets consists of melt spinning the alloy to produce ribbons, milling of melt-spun ribbons to powder, followed by hot pressing and die upsetting.¹⁻⁴ The optimally quenched melt-spun ribbons have equiaxed and randomly oriented Nd₂Fe₁₄B (2-14-1) grains. Hot pressing of ribbon powder achieves complete densification and a desired shape while maintaining essentially an isotropic structure and magnetic properties. The subsequent hot deformation process modifies the equiaxed grains to platelets with increase in grain size. These platelets are stacked with the *c* axis perpendicular to the face of the grains. The mechanism of *c*-axis alignment has been suggested to be by a combination of grain-boundary sliding and anisotropic grain growth in a direction normal to the applied stress.^{5,6} The amount of *c*-axis alignment with the press direction, measured using x-ray diffraction techniques, has been shown to depend on the amount of deformation. In addition, the strain distribution in a magnet deformation at a given level is expected to be non-uniform due to friction between the die wall and the magnet. The friction coefficient between the die wall and magnet is sensitive to the surface conditions, deformation temperature, the lubricant, and the load. Thus, depending on the die-upset process conditions, the stress and strain distribution will vary and this is expected to influence the texture, and hence, the magnetic properties. The nature of the strain and stress distribution in the magnet during the different stages of the upset deformation is very critical in understanding the texture development in these magnets. To the best of our knowledge, no detailed analysis of how the local stress and strain

influence the crystallographic alignment by grain-boundary sliding and anisotropic grain growth has thus far been performed. In this work, an assessment of stresses and strains in the magnet is made by a simulation of the die-upset process and is correlated with texture measurements made using x-ray diffraction.

II. EXPERIMENTAL WORK

NdFeB magnets were die upset to 50%, 60%, and 70% deformation and the texture in these magnets were evaluated using x-ray pole figures. Simulation of the die-upset process for NdFeB magnets was done using "ANTARES," a finite-element-based plastic deformation modeling software for the cases of 50%, 60%, and 70% upsets. An initial strain rate of 2×10^{-2} and a temperature of deformation of 800 °C was assumed. The material was assumed to exhibit a deformation behavior by the equation

$$\sigma = \sigma^0 + k \epsilon^n \dot{\epsilon}^m,$$

where σ^0 = flow stress at $\epsilon=0$, k =constant, ϵ =strain, $\dot{\epsilon}$ = strain rate, n =strain hardening factor, and m =strain rate sensitivity factor. For the die material, the property data used corresponded to H-11 tool steel. The data for Nd-Fe-B used were obtained from the work of Yoshikawa *et al.*⁷ A friction coefficient of 0.3 was used for the magnet/die interface lubricated with graphite.

III. RESULTS AND DISCUSSION

Typical deformation geometry used for die-upset simulation is shown in Fig. 1(a). The diameter of the billet is 18 mm and the length of the billet varies slightly depending on

(a)

(b)

FIG. 1. Typical deformation (a) at the end of the die upset and (b) at an intermediate stage of the die upset. Axis of symmetry is along the left edge. A, B, and C refer to the magnet, top punch, and bottom die, respectively.

the die upset required. Each % upset requires a different die set with appropriate diameter and depth of the cavity. The geometry of the billet at each incremental step of the punch movement can be obtained, and Fig. 1(b) presents the billet mesh geometry at an intermediate stage of the die-upset process. The barreling of the billet results from (i) the friction at the top punch/billet interface and the die/billet interface, and (ii) the temperature variation across the billet due to heat transfer across the die-billet interfaces and billet/protective gas interface. Near the end of the deformation process, the barreled surface of the billet makes contact with the lateral faces of the die, and the flow patterns in peripheral regions become complex. The values of different stress, strain, strain energy, temperature, and other parameters are obtained at every stage of the process. Of importance are the principal stress and effective strain values. The principal stress is nearly parallel to the axis of the magnet and the effective strain is proportional to the strain in the direction parallel to

FIG. 2. Principal stress contours at the end of 60% die-upset deformation.

the axis of the billet (ϵ_{zz}). Figures 2 and 3 present the principal stress and effective strain contours in the magnets at the end of deformation for the 60% die-upset magnets. It has been observed that grain growth along the a axes that are normal to the applied stress is favored. The principal stress-time-temperature profile is thus important in assessing the contribution of the anisotropic growth. The effective strain could also be more directly correlated with the grain rotation and anisotropic grain growth, and the crystalline alignment. For the case of the 50% die-upset magnet (Fig. 4), the effective plastic strain varies from 53.27% at the center of the bottom and top face to a value of 79.81% at the central region of the magnet. This suggests that the crystalline texture must vary significantly across the magnet. For the case of 60% deformation (Fig. 3), the effective strains at all the different locations have increased. At the center of the bottom and top faces, the effective strain is 59.29% compared to the value of 53.27% for 50% deformation. The center of the magnet experienced an effective strain of 107.62%. For the 70% upset magnet (Fig. 5), these values increased to 71.74% for the center of the top and bottom faces and 145.91% for the central region of the magnet. In these three figures, the lateral confinement by the cylindrical bottom die face, and

FIG. 3. Effective strain contour at the end of 60% die-upset deformation.

FIG. 4. Effective strain contour at the end of 50% die-upset deformation.

the extrusion of the magnet through the clearance between the punch and bottom die result in a highly nonuniform strain distribution in the corner regions. The average strain level increases with the increase in the percentage of the die upset, and therefore, the overall texture should increase with percentage of the die upset. However, the large variation in the effective strain should also lead to extensive variation in texture across the magnet, and therefore, the magnetic properties are expected to be nonuniform. There may, however, be a critical effective strain level above which there is no further improvement in texture. If this critical level is exceeded at all the locations of the magnet, then a complete or limiting (006) texture would have been achieved. The effective strain variation in the radial direction is much less compared to the variation in the thickness direction, except for the region near the edge of the magnet.

The deformation modeling work is consistent with the texture measurements made in these die-upset magnets. The

FIG. 5. Effective strain contour at the end of 70% die-upset deformation.

FIG. 6. Three-dimensional partial (006) pole figure from (a) 0.5 mm depth and (b) 1.0 mm depth of the 60% die-upset magnet.

(006) pole figures from a 0.5 mm depth are shown in Fig. 6(a) and those for a 1.0 mm depth are shown in Fig. 6(b). Their W_{50} values are 26.3° and 24.0° for the 0.5 and 1.0 mm depths, respectively. They again show that the crystallographic alignment is enhanced as one moves from the surface toward the center of the magnet. This observation is as expected from the deformation modeling. The larger strain produced a stronger (006) texture. It also suggests that friction between the sample and punch affects the crystal alignment near the sample surface. The results from the modeling work are also consistent with the study of texture variation across the die-upset magnets by Lewis *et al.*⁸

High energy density magnets $>400 \text{ kJ/m}^3$ are increasingly used in many applications. Conventional casting techniques for sintered magnets reveal the formation of a high quantity of α -Fe and large Nd-rich regions. New techniques, like strip casting, produce homogeneous and fine scaled microstructures and are already used for producing high $(BH)_{\max}$ magnets. The fast cooling rate during strip casting suppresses the formation of α -Fe dendrites and of large Nd-rich pockets. Directional solidification causes a formation of columnar grains containing a typical arrangement of hard magnetic $\text{Nd}_2\text{Fe}_{14}\text{B}$ regions and Nd-rich regions. The Nd regions occur as intragranular platelets as well as intergranular phases. Intragranular lamellae show a periodicity which corresponds to a eutectoidal solidification according to the composition of the liquid and are directed parallel to the temperature gradient during solidification. The lamellae show an average width of 150 nm, a spacing of 3 μm , and a length up to the size of the hard magnetic grains. The fine separation of the hard magnetic and Nd phases is advantageous for the milling of the alloy after hydrogen decarburization and improves sinterability of magnets. Although the microstructure of strip cast alloys is much finer than that of ordinary cast alloys, the alignment of the powder is not deteriorated and B_r is not reduced due to a sufficient large interlamellar spacing between the Nd-rich platelets that enables the formation of single crystal powder particles after milling. © 1998 American Institute of Physics. [S0021-8979(98)18911-9]

I. INTRODUCTION

Sintered Nd–Fe–B-type permanent magnets are widely used in applications that require a high energy product/volume ratio in order to reduce weight.¹ In addition there is a rising demand for magnets with $(BH)_{\max}$ higher than 400 kJ/m^3 . This goal can be reached by shifting the alloy composition more towards the stoichiometric $\text{Nd}_2\text{Fe}_{14}\text{B}$ composition as well as by improving the alignment of the hard magnetic grains during compacting. In addition the distribution of phases in the starting alloy can be significantly improved. Conventional casting techniques reveal the formation of a high quantity of precipitated α -Fe that deteriorates the powder alignment² and large Nd-rich regions that are very sensitive to oxidation. The α -Fe is formed according to the pseudo-binary Fe–(Nd,B) phase diagram, with Nd:B = 2:1, where the solidification path passes through a region (Liq. + Fe) and Fe particles are formed within the liquid.³ The formation of dendritic α -Fe in cast alloys can be reduced by additives like M2=Ti, Nb, Zr, V, Mo, or W that form M2–Fe–B borides⁴ as well as by optimizing the casting technique. It has been previously shown that flat cast ingots consist of fine grains near the mold surface, columnar grains in the central portions, and coarse grains near the free surface.⁵ Reducing the thickness of the ingots from 8.7 to 4.4 mm resulted in an increase of the amount of columnar grains

and in a decrease of dendritic α -Fe in the ingot. An improvement of B_r by 5% and $(BH)_{\max}$ by 10% of magnets produced from that ingot were attributed to a significantly reduced presence of dendritic α -Fe causing a better grindability of the powder and a better grain alignment. In this article we report on the effect of strip casting on the microstructure of Nd–Fe–B magnetic material. Materials produced by strip casting are already used for high $(BH)_{\max}$ magnets. This new technique allows large scale production of ingots with a homogeneous and fine scaled microstructures without a significant precipitation of α -Fe. The fine dispersion of the rare earth-rich phase is important not only for high energy magnets having $(BH)_{\max}$ of over 400 kJ/m^3 , but also for high coercivity magnets that include high Dy concentrations. In such strip cast high Dy alloys B_r and $(BH)_{\max}$ are improved keeping the coercive field high because the total rare earth content can be substantially decreased without the formation of rare earth depleted regions that can deteriorate the squareness of the demagnetization curve of sintered magnets.

II. EXPERIMENT

The investigated samples with the composition $(\text{Nd,Dy})_{14.1}(\text{Fe,Al})_{80}\text{B}_{5.9}$ were produced by strip casting, a technique similar to melt spinning, using a wheel speed of 1 m/s. The platelike casted alloy shows a typical thickness of 250–350 μm and a width of several centimeters. The samples were investigated by optical microscopy with polar-

FIG. 1. Optical micrograph of the cross section of strip cast $(\text{Nd,Dy})_{14.1}(\text{Fe,Al})_{80}\text{B}_{5.9}$ showing the columnar growth of hard magnetic grains starting at nucleation centers (C) and the magnetic domains structure inside the columnar grains.

ized light as well as by scanning electron microscopy (SEM) and transmission electron microscopy (TEM).

III. RESULTS AND DISCUSSION

The typical microstructure of the strip cast alloy parallel to the direction of solidification observed with polarized light is shown in Fig. 1. Solidification of the melt starts at nucleation centers (C) at the wheel side of the strips. The distance between individual centers is 50–120 μm . Starting from these nucleation sites, a columnar structure of hard magnetic grains is formed due to directional solidification. The growth direction of the grains is typically the direction of the heat flow during solidification. The columns grow within a cone with an opening angle 60°–80° towards the free surface of the strips. The diameter of the individual grains perpendicular to the growth direction is 5–25 μm close to the wheel side and 25–60 μm close to the free surface side (Fig. 2), respectively.

The columnar grains consist of a hard magnetic phase, which is proven by the existence of the magnetic domain pattern in that structure. The orientation of the domain walls visible with polarized light indicates that the growth direction of these columns within the cone does not correspond with either $\langle 100 \rangle$, the easy growth axis of the tetragonal 2:14:1 structure,^{6,7} or $\langle 001 \rangle$. A columnar dendritic 2:14:1 structure with a growth direction parallel to $\langle 001 \rangle$ was pre-

FIG. 2. Optical micrograph taken parallel to the surface of the strips near the free surface side.

FIG. 3. SEM micrograph of the polished cross section of the strip cast alloy showing the distribution of hard magnetic phase (dark) and Nd-rich phase (bright) in backscattered mode.

viously observed in splat cooled $\text{Nd}_{15}\text{Fe}_{77}\text{B}_8$ magnets.⁸ A preferred c axis texture normal to the ribbon plane was also observed in melt spun $\text{Nd}_{16}\text{Fe}_{76}\text{B}_8$ ribbons.⁹ Close to the wheel side between the nucleation sites, smaller elongated grains are formed with a growth direction more parallel to the surface. In these grains the domain walls tend to be oriented perpendicular to the surface, indicating a preferred $\langle 100 \rangle$ growth direction of the magnetic grains in that region. Within the large dendritic columns of the 2:14:1 phase a thin plateletlike phase is formed parallel to the growth direction. The occurrence of this intragranular layered structure does not usually influence the domain structure of the hard magnetic grains (compare Fig. 1). Figure 3 shows a SEM backscattered electron micrograph of a strip cast sample perpendicular to the wheel side. The hard magnetic grains appear as dark areas. Thin bright regions which occur with a certain periodicity within the hard magnetic grains and at grain boundaries consist of the Nd-rich phase. There is no indication for the formation of dendritic $\alpha\text{-Fe}$ or a significant amount of additional phases like $\text{Nd}_{1+x}\text{Fe}_4\text{B}_4$ formed during solidification. The lamellar arrangement of the two phases that are oriented parallel to the temperature gradient is characteristic for a eutectoidal solidification. The interlamellar spacing between the Nd-rich platelets is about 3 μm and is controlled by the temperature gradient during solidification as well as the composition of the liquid.

The orientation relationship between the Nd-rich intragranular platelets and hard magnetic matrix grains was further investigated by TEM. Figure 4 shows the typical microstructure of a columnar 2:14:1 grain in the center of a strip viewed perpendicular to the direction of solidification. Hard magnetic grains are separated by intragranular Nd-rich lamellae with a thickness of 60–150 nm. Within a grain all hard magnetic regions show the same crystallographic orientation. Close to grain boundaries the Nd-rich intragranular regions are also found with more irregular shapes.

At grain boundaries and especially at grain boundary junctions, intergranular Nd-rich phases are found. Selected area electron diffraction (SAD) confirms that the Nd-rich platelets as well as the intergranular Nd-rich phases mainly occur as fcc Nd and less frequently as Nd oxide. X-ray spectra show that there is usually a significant amount of Fe

FIG. 4. TEM micrograph of strip cast $(\text{Nd,Dy})_{14.1}(\text{Fe,Al})_{80}\text{B}_{5.9}$ showing intragranular Nd-rich platelets embedded in a hard magnetic grain. The diffraction pattern of the marked region shows diffraction spots from the tetragonal $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase and of the fcc Nd-rich lamella.

dissolved within the Nd-rich phases. During the TEM investigation no $\alpha\text{-Fe}$ or $\text{Nd}_{1+x}\text{Fe}_4\text{B}_4$ was detected. The analysis of various diffraction patterns revealed that most of the lamellae are formed parallel to the $\{1,1,-1\}$ plane of the tetragonal 2:14:1 phase.

Good magnetic properties require a homogeneous distribution of all phases and dopant elements throughout the cast material. Traditional casting techniques can cause a segregation of individual phases depending, e.g., on the geometry of the casting mold, composition, or cooling rate, and therefore lead to strong inhomogeneities of the microstructure and the chemical composition.^{2,5,10} The strip casting technique enables a fine separation of hard magnetic and rare earth-rich phases in the cast alloys. The merits of using strip cast alloys as a starting material for high performance Nd-Fe-B magnets are as follows:

(1) The rapid solidification process prevents the formation of large dendritic $\alpha\text{-Fe}$ grains in the cast alloy without the need of isothermal annealing even if the total rare earth content is reduced in order to produce high $(\text{BH})_{\text{max}}$ mag-

nets. The sufficiently large interlamellar spacing of about $3\text{ }\mu\text{m}$ between the Nd-rich platelets in the columnar $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains is crucial in order to enable the formation of single crystal powder particles after HD treatment and jet milling necessary for optimum alignment of the particles and for high Br in the magnets.

(2) The homogeneous fine scale microstructure, containing a high amount of thin rare earth-rich platelets, leads to a high density of fine pre-cracks after hydrogen decrepitation. That and the lack of large dendritic $\alpha\text{-Fe}$ grains improves the crushability of strip cast alloys significantly.

(3) The good dispersion of rare earth-rich phases in the strip cast alloys leads to an optimum distribution of liquid phase during sintering and enables the production of high density magnets with high coercive fields even at lower sintering temperatures. The total rare earth content can be decreased by using strip casting without the formation of rare earth depleted zones in the magnets. That is essential for high $(\text{BH})_{\text{max}}$ magnets but also in the case of magnets with high Dy content in order to improve the remanence and $(\text{BH})_{\text{max}}$ while keeping high iH_c .

Extension of the primary solidification region of $\text{Nd}_2\text{Fe}_{14}\text{B}$ by levitation of undercooled melts

R. Hermann^{a)} and W. Löser

Institute of Solid State and Materials Research (IFW), Institute of Metallic Materials, Helmholtzstrasse 20, D-01069 Dresden, Germany

Undercooled Nd–Fe–B melts with compositions near the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase (Φ phase) were studied by the electromagnetic levitation technique. *In situ* measurements of the solidification kinetics were accomplished and melt drops with controlled undercooling were quenched onto chill substrates in order to reveal the solidification sequence and microstructure formation processes. Crystal growth velocities of the Φ phase of the order of 1 mm s^{-1} were estimated from *in situ* measurements. Consistent with the nucleation theory, which predicts primary γ -Fe phase crystallization up to 650 K undercooling for the stoichiometric alloy, γ -Fe nucleation could not be avoided during undercooling but the quenching of the melt drops led to dissolution of the γ -Fe nuclei during Φ -phase formation. The γ -Fe phase growth was suppressed in a seam adjacent to the chill surface, whereas Fe dendrites occurred in the remaining parts of the quenched samples. Reduced solute rejection on growth is believed to be responsible for the preferred metastable Φ -phase formation from the undercooled melt on chill substrates. The investigation gives some clues to understand different microstructures and magnetic properties of powder precursors for permanent magnets obtained from different rapid solidification routes. © 1998 American Institute of Physics. [S0021-8979(98)15111-3]

I. INTRODUCTION

Commercial Nd–Fe–B permanent magnets are usually prepared by sintering or rapid quenching methods.^{1,2} The $\text{Nd}_2\text{Fe}_{14}\text{B}$ compound exhibits a high saturation magnetization and a strong magnetocrystalline field. These properties are the physical conditions for excellent permanent magnets. However, different magnetic properties are obtained using various processing techniques due to different microstructure. The determination of the crystallization behavior and the resulting microstructure are still under study. Detailed knowledge of the solidification behavior is essential especially for the development of alloys with novel properties. The solidification processes in rapid solidification techniques are hardly accessible to direct observation. Therefore, the purpose of this article was a study of crystallization processes of Nd–Fe–B melts by the containerless electromagnetic levitation method. This technique permits *in situ* measurements of the solidification kinetics of undercooled melt drops during the recalescence stage. Moreover, melt drops with controlled undercooling levels have been quenched onto copper substrates and copper–tin-coated substrates, respectively, in order to reveal the as-solidified microstructure.

II. EXPERIMENT

Three different Nd–Fe–B master alloys were prepared from pure Nd and Fe–B alloy by arc melting under argon atmosphere. Composition A is the stoichiometric $\text{Nd}_{11.8}\text{Fe}_{82.3}\text{B}_{5.9}$ alloy. Composition B is a hypostoichiometric $\text{Nd}_{11}\text{Fe}_{83.5}\text{B}_{5.5}$ alloy and composition C is a hyperstoichiometric $\text{Nd}_{15.8}\text{Fe}_{76.3}\text{B}_{7.9}$ alloy. Spheres of about 6 mm

in diameter and about 1.2 g mass were containerless melted and solidified in an electromagnetic levitation facility under helium gas atmosphere. The melted samples were cooled by a gas stream enabling cooling rates of about 10 K s^{-1} . The temperature of the sample was monitored by a two-colorpyrometer with a sampling rate of 50 Hz and a relative accuracy of $\pm 3 \text{ K}$. For measuring and resolving the fast recalescence time a modified single-reflex camera with a silicon diode in its focal plane was used enabling sample rates of 500 MHz. The sampling rate of the transient recorder was 1.5 MHz. A detailed description of the facility is given elsewhere.³ Melt drops of well defined undercooling level were quenched on a copper substrate and a copper substrate which was coated with tin to enhance the interfacial heat transfer. Immediately after nucleation the drops solidify with a preferred heat flow into the undercooled melt but with a heat transfer into the chill substrate as well. The as-solidified melt drops were investigated by digitally enhanced Kerr microscopy and scanning electron microscopy.

III. RESULTS

A. Time-temperature characteristic

The solidification of the undercooled melt drop starts by spontaneous nucleation or can be initiated by triggering at a well defined undercooling level. The photodiode does not, in principle, allow one to determine an absolute temperature, but the two-color pyrometer could be used to set the temperature scale in order to compare the results with the equilibrium phase diagram. Figure 1 shows typical temperature-time profiles of the three investigated Nd–Fe–B compounds. The stoichiometric sample [Fig. 1(a)] was melted at $T_m = 1520 \text{ K}$ and initially superheated. After cooling down be-

^{a)}Electronic mail: R.Hermann@IFW-Dresden.de

FIG. 1. Temperature-time characteristic of double recalescence events of: (a) a stoichiometric Nd-Fe-B alloy at an undercooling level of 170 K (with respect to the liquidus temperature), (b) a hypostoichiometric Nd-Fe-B alloy at an undercooling level of 165 K, (c) a hyperstoichiometric Nd-Fe-B alloy at an undercooling level of 130 K.

low the melting temperature, the solidification of the sample occurs at 1350 K, corresponding to an undercooling level of $\Delta T = 170$ K. The solidification process consists of two steps. The first step can be attributed to a small amount of γ -Fe phase nuclei at about 1460 K, whereas the drop is still under undercooling. The second step starts with the solidification of the Φ phase. Assuming that the solidification front is planar, the growth velocity of the Φ phase can be estimated to 1.2 mm s^{-1} . The resulting time of crossing the planar front through the viewing field of the diode ($0.88 \text{ mm} \times 0.88 \text{ mm}$) was measured to 720 ms. Figures 1(b) and 1(c) show the corresponding temperature-time profile of the hypostoichiometric and hyperstoichiometric sample, respectively. It is of interest to note that all three alloys show the small recalescence step of γ -Fe phase nucleation independent of the achieved undercooling level.

B. Phase analysis of as-solidified samples

The *in situ* observation of undercooled melts is an important tool for investigation of rapid solidification. Nevertheless, the microstructure of the as-solidified sample has to be investigated. The arc-melted master alloys show different microstructures. In alloys A and B γ -Fe dendrites are clearly visible whereas alloy C does not contain any γ -Fe dendrites. Figure 2 shows the backscattering electron (BSE) micrographs of a sample of alloy B, undercooled at about 150 K prior to solidification and subsequently quenched on a copper-tin-coated substrate. Immediately on the strongly separated tin layer a nonfeatured layer of about $100 \mu\text{m}$ has been developed, responsible for pure metastable Φ phase electron probe microanalysis investigation, Fig. 2(a)]. The relatively sudden transition to the structured layer shows the beginning decomposition into Fe-rich phases and the growth of $\text{Nd}_2\text{Fe}_{14}\text{B}$ needles [see Figs. 2(a) and 2(b)]. Finally, the growth of Fe dendrites and the separation of Nd-rich phases in the interdendritic region indicate the transition to equilibrium solidification [Fig. 2(c)].

FIG. 2. BSE micrographs of alloy B, undercooled at about 150 K prior to chilling on a copper-tin-coated substrate: (a) featureless $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase layer near the chill substrate, (b) growth of $\text{Nd}_2\text{Fe}_{14}\text{B}$ needles and Fe-rich phases, (c) growth of Fe dendrites near the top of the sample.

On the other hand BSE micrographs of samples quenched on a copper substrate prior to solidification, show that Fe dendrites have been grown directly in the quenched region. The heat transfer was not sufficient for the formation of pure metastable Φ phase even at the stoichiometric alloy. These microstructures indicate that both critical undercooling and rapid quenching are necessary for the growth of the metastable Φ phase.

IV. DISCUSSION

The as-solidified microstructure of Nd-Fe-B alloys is determined by nucleation and growth processes of the competitive phases, notably γ -Fe and Φ phase, and post-solidification transformations as well. The homogeneous nucleation rates of γ and Φ phase, I_γ and I_Φ , respectively were estimated as functions of melt undercooling on the basis of thermodynamic and kinetic data given by Clavaguera and Diego.⁴ For the stoichiometric melt composition, the nucleation of the peritectic γ -Fe phase dominates in a wide undercooling range below the liquidus temperature $T_{l,\gamma}$. The crossing point with the I_Φ is about 650 K below the liquidus temperature, outside the range of experimental accessibility. In principle, the nucleation and growth of the Φ phase can arise in the primary γ -Fe phase field well above the peritectic temperature if a critical undercooling below the metastable liquidus temperature $T_{l,\gamma}$ is achieved.^{5,6} The time-temperature characteristics of levitated samples indicate that γ -Fe nucleation could not be avoided on slow cooling of the levitated samples. This becomes apparent from the small dip near the liquidus temperature $T_{l,\gamma}$. The residual melt, however could be undercooled by a considerable amount of >170 K below $T_{l,\gamma}$. Accordingly a very distinct recalescence event was obtained due to the growth of the Φ phase from the undercooled melt. The microstructural features indicate that both melt undercooling and fast cooling were necessary for the growth of the metastable Φ phase. Quenching of the undercooled melt drops onto the copper-tin-coated substrate led to a wide seam of more than $100\ \mu\text{m}$ thickness free of γ -Fe dendrites even for hypostoichiometric melt alloys. More distant from the chill surface the growth of $\text{Nd}_2\text{Fe}_{14}\text{B}$ needles continued with apparent Fe segregation in the interdendritic regions before γ -Fe dendrites indicate the transition to the equilibrium solidification mode. The reason

for the possible suppression of the γ -Fe equilibrium phase dendrites and preferred growth of the metastable Φ phase is its smaller composition deviation from the melt, which leads to less solute rejection at the growth front.⁶ This behavior is typical of various peritectic alloys.⁷ This first attempt of Nd-Fe-B melt undercooling experiments shed some light onto the obvious differences in microstructure and magnetic properties of powder precursors for Nd-Fe-B hard magnetic materials obtained from different rapid solidification techniques. In hyperstoichiometric inert-gas-atomized Nd-Fe-B particles peritectic γ -Fe precipitations depending on droplet size were found,⁸ whereas thin melt spun ribbons often exhibit an overquenched amorphous state from which the Φ phase can evolve. There is an apparent difference in the thermal history of both rapid solidification techniques. IGA particles are exposed to moderate cooling rates of 10^3 – $10^5\ \text{K s}^{-1}$ by the gas stream. High undercooling of droplets prior to solidification is expected, which is a behavior similar to levitated samples. In melt spinning there is a vigorous heat transfer from a thin melt film to the chill substrate, which can lead to a dynamic undercooling and finally quenching the melt into the amorphous state before nucleation of crystalline phases because of cooling rates as high as $10^6\ \text{K s}^{-1}$.

High performance Nd-Fe-B sintered magnets made by the wet process

M. Takahashi,^{a)} K. Uchida, and F. Taniguchi

Magnetic and Electronic Materials Research Laboratory, Hitachi Metals, Ltd. 5200 Mikajiri, Kumagaya, Saitama 360, Japan

T. Mikamoto

Production System Laboratory, Hitachi Metals, Ltd., 6010 Mikajiri, Kumagaya, Saitama 360, Japan

The wet process for the fabrication of Nd-Fe-B sintered magnets has been developed on the mass production scale. In this process, mineral oil is used as a solvent to prevent the milled powder and green bodies from oxidation. It is removed before sintering. As a result, the oxygen uptake during storage is less than 0.01 wt %/day. By reducing the oxygen content and the total rare earth (TRE) content in sintered magnets to less than 0.2 and 29.3 wt %, respectively, magnets with $(BH)_{\max}/H_c$ greater than 50 MGOe/10 kOe, 45 MGOe/15 kOe, and 32 MGOe/32 kOe were obtained with high reliability. The magnets produced by this wet process also show better corrosion resistance and 20% higher mechanical strength than those made by conventional methods. These characteristics may be explained by a smaller grain size, smaller TRE content, and higher density produced by the wet process. © 1998 American Institute of Physics. [S0021-8979(98)15211-8]

I. INTRODUCTION

Nd-Fe-B sintered magnets with higher magnetic properties have been required as their applications decrease in size. Minimizing nonmagnetic secondary phases (rare earth oxide, B-rich phase etc.), maximizing grain alignment, and optimizing alloy design are ways to increase $(BH)_{\max}$ of Nd-Fe-B sintered magnets, and concrete methods based on these principles have been presented.^{1,2} Improving the magnetic properties by minimizing nonmagnetic secondary phases requires a reduction in the oxygen content in sintered magnets. To reach this goal, various methods have been developed for the powder metallurgy process. However, it is difficult to prevent oxidation in chemically active fine powder and green compacts that are exposed to the air with conventional methods. A low oxygen content of around 0.2 wt % in a sintered body could be achieved only on the laboratory scale by a wet process using an organic solvent such as *n*-hexane or a dry process using oxygen-free chambers and containers.

We have developed a wet process (HILOP, HITACHI low oxygen process) using mineral oil as a solvent and have obtained Nd-Fe-B sintered magnets with less than 0.2 wt % oxygen in sintered bodies on the production scale. In this article, the procedure of the developed wet process and the characteristics of the resultant magnets will be presented.

II. EXPERIMENT

The developed wet process is based on conventional powder metallurgy techniques, but is distinguished from the conventional technique by handling the milled powders and green bodies in oil from milling to sintering. The wet process procedure is illustrated in Fig. 1 in comparison with the conventional dry process. Cast alloys were annealed at 1100 °C for 6 h, and then ground to less than 500 μm after the hy-

drogen decrepitation process. The oxygen content in the nitrogen gas used in the mill chamber for conventionally processed materials is commonly around 1000 ppm to stabilize the surface of the fine powder to prevent rapid oxidation in air. In the wet process, however, the prepared coarse powders were jet milled with no oxygen (less than the detection limit, i.e., <0 ppm). Milled powders were put in mineral oil without being exposed to the air, mixed into slurries, and stored for pressing. The slurries were die-pressed in a magnetic field of 14 kOe applied perpendicular to the axis of the press. The extremely low vaporization rate of the oil compared to that of organic solvents such as *n*-hexane enables the green bodies to be handled in air. The oil present in the green bodies was removed in the temperature range 100 °C $\leq T \leq$ 300 °C for 1 h in a vacuum of 10^{-1} Torr before sintering. Sintering was carried out at temperatures from 1050 to 1080 °C in a vacuum of 10^{-5} Torr for 5 h. Sintered bodies were heat-treated at 900 °C for 2 h followed by another heat treatment at temperatures from 460 to 560 °C for 1 h. Magnetic properties were measured by a *B-H* tracer. Corrosion rates were determined by measuring the weight losses after exposing the magnets in an autoclave under conditions of 120 °C, 100% relative humidity, and 2 atm.

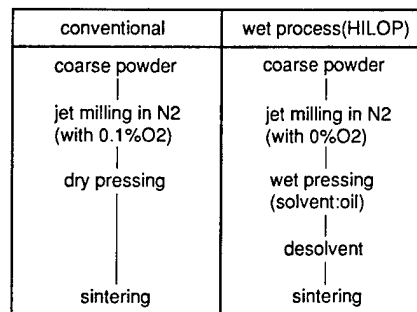

FIG. 1. A comparison of the wet process (HILOP) with the conventional dry process.

TABLE I. Typical oxygen and carbon contents of HILOP-processed and conventionally processed materials.

Process	Oxygen (wt %)	Carbon (wt %)
HILOP	0.16	0.061
Conventional	0.58	0.055

III. RESULTS AND DISCUSSION

A. Oxygen contents and magnetic properties

The typical oxygen and carbon contents of magnets with compositions of

and

in wt % produced by the wet process and the conventional dry process, respectively, are shown in Table I. The final carbon content of the wet-processed magnets is only around 0.01 wt % greater than that of conventionally processed magnets. This indicates that the oil remaining in the green body was well removed by the desolvent process. The oxygen content of wet-processed materials is less than a third of that of the magnets produced by the conventional process. The oxygen content increased by only 0.02 wt % from the starting coarse powder with 0.14 wt % oxygen during jet milling, pressing, desolventing, and sintering process steps. The oxygen uptake rate for wet-processed powders stored in oil was much lower than that for powders stored in organic solvent (*n*-hexane): 0.007 and 0.016 wt %/day, respectively. The characteristics of oxidation prevention and low vaporization rate of the oil contribute to the adaptation of the wet process to mass production with high reliability. The low final oxygen levels provided by the wet process raised the possibility of a reduction of total rare earth (TRE) content.

Figure 2 shows variations of iH_c with oxygen content for sintered magnets with different TRE contents. The coercivity iH_c decreased with the increase of oxygen content. As TRE decreased from 29.8 to 28.9 wt %, the iH_c decrease rate for the oxygen content in the range 0.15 wt % \leq O \leq 0.25 wt % became higher and iH_c was deteriorated to zero with a lower

FIG. 2. Variations of iH_c with oxygen content for sintered magnets with different TRE contents: (a) 29.8 wt %, (b) 29.3 wt %, (c) 28.9 wt %.

FIG. 3. Magnetic properties of HILOP materials (a) in comparison with conventionally processed materials (b).

oxygen content. This is due to a reduction of the Nd-rich phase caused by the change from Nd to Nd oxide. To obtain a high enough iH_c for practical use, a TRE of more than 29.3 wt % is required.

Figure 3 shows the magnetic properties of HILOP materials for 29.3 wt % TRE

($x = 1.5, 3.0, 4.5, 5.5, 7.5, 9.5$) in wt %] in comparison with conventional compositions (TRE = 31.5–32.5 wt %) on the production scale. From high Br to high iH_c , Br of HILOP materials is 800 G higher than that of conventionally processed materials, due to lower oxygen content and lower TRE content. The HILOP process is also applicable to materials with a much higher $(BH)_{\text{max}}$. The magnetic properties of $(BH)_{\text{max}} = 51.0$ MGOe with $iH_c = 13.1$ kOe were obtained for the composition of

B. Corrosion resistance

The corrosion resistance of the HILOP materials containing less than 0.2 wt % oxygen was investigated. The weight loss of the HILOP material ($\text{Nd}_{27.1}\text{Pr}_{0.6}\text{Dy}_{1.5}\text{Fe}_{\text{bal.}}\text{Co}_{2.1}\text{Nb}_{0.7}\text{Ga}_{0.1}\text{Cu}_{0.1}\text{B}_{1.1}$) is shown in Table II in comparison with a conventionally processed material ($\text{Nd}_{23.9}\text{Pr}_{6.6}\text{Dy}_{1.4}\text{Fe}_{\text{bal.}}\text{Nb}_{0.7}\text{Ga}_{0.1}\text{B}_{1.0}$) and a reference material ($\text{Nd}_{28.2}\text{Pr}_{2.2}\text{Dy}_{1.2}\text{Fe}_{\text{bal.}}\text{Nb}_{0.5}\text{Ga}_{0.1}\text{B}_{1.1}$) that has almost the same TRE as the conventionally processed material and almost the same oxygen content as HILOP material. The weight loss rate of the magnet with a TRE of around 32 wt % increased with decreased oxygen content. This trend is in agreement with those reported by Kim³ and Camp.⁴ How-

TABLE II. Weight loss of HILOP material by pressure cooker test (P.C.T.) for 96 h in comparison with the conventionally processed material. The materials' compositions are given in the text.

Process	TRE (wt %)	Oxygen (wt %)	Weight loss (mg/cm ²)
Conventional	31.7	0.75	0.67
Ref.	31.9	0.15	21.12
HILOP	29.2	0.15	0.53

FIG. 4. Photos showing the microstructure of HILOP material (a) in comparison with a conventionally processed magnet (b).

ever, the HILOP material shows a lower weight loss rate even compared to that of the conventionally processed material in spite of its low oxygen content.

Figure 4 shows optical micrographs of the HILOP material and the conventional material. Compared to the conventional material, the HILOP material has a smaller and more homogeneous grain size, so the Nd-rich phases (black or gray regions in the micrographs) at the triple junctions are smaller and more homogeneously distributed. According to the article by Scott *et al.*,⁵ the weight loss rate decreases with the decrease of grain size. Since the corrosion of Nd-Fe-B sintered magnets is initiated in the Nd-rich grain boundary phase,^{6,7} the above result may be explained by the fact that the magnet possesses a lower TRE and that the Nd-rich phases are more evenly distributed, with smaller grain size.

C. Mechanical strength

Table III shows the three-point bending strength and the density of sintered bodies of HILOP material ($\text{Nd}_{21.3}\text{Pr}_{0.5}\text{Dy}_{7.5}\text{Fe}_{\text{bal.}}\text{Co}_{2.0}\text{Nb}_{0.7}\text{Ga}_{0.1}\text{Cu}_{0.1}\text{B}_{1.0}$) and the conventionally processed material

The mechanical strength of HILOP material is improved by around 25%. This result may be attributed to the smaller

TABLE III. Three-point bending strengths and densities (ρ s) of HILOP material in comparison with those of the conventionally processed material.

Process	ρ s (g/cm ³)	Three-point bending strength (kgf/mm ²)
Conventional	7.62	26.2
HILOP	7.70	32.8

grain size mentioned above, higher density (i.e., fewer voids) and fewer inclusions in the Nd-rich phase, such as rare-earth oxides. This issue requires further investigation.

IV. CONCLUSION

The wet process using mineral oil to prevent milled powder and green bodies from oxidation has been established. As a result, magnets with oxygen content of less than 0.2 wt % and $(BH)_{\text{max}}$ of higher than 45 MGOe were obtained in production. The above magnets also have a better corrosion resistance and a higher mechanical strength mainly due to a smaller grain size and a smaller TRE content in the sintered bodies. This process has produced a reduction in the final oxygen content during production, and is one approach for the production of high performance Nd-Fe-B sintered magnets. Additional improvements in the crystallographic alignment of the magnets will produce magnets with much higher magnetic properties.

Hydrogen absorption and desorption behavior in Pr-Fe-B type alloys

Yoon B. Kim and W. Y. Jeung

Center for Metal Processing, Korea Institute of Science and Technology, P.O. Box 131 Cheongryang, Seoul 130-650, Korea

In this study, the hydrogen absorption and desorption behavior of Pr-Fe-B type alloys with addition of Co, Ga, and Zr was investigated focusing on the disproportionation and recombination reaction in HDDR process. In $\text{Pr}_{13}\text{B}_6\text{Fe}_{\text{bal}}$ alloy, the second hydrogen absorption reaction which corresponds to the disproportionation reaction in HDDR process occurs at about 620 °C, and the recombination reaction was not observed below 1000 °C in hydrogen atmosphere. In alloys with Co content of 12 at.%, the second hydrogen desorption reaction, which corresponds to the recombination reaction in HDDR process, occurs at about 955 °C and the occurring temperature of the recombination reaction is further decreased with increasing Co content. The Ga addition to $\text{Pr}_{13}\text{B}_6\text{Fe}_{\text{bal}}$ alloy also reduces the recombination reaction temperature and has no significant influence on the disproportionation reaction. Moreover, the lowering of the recombination reaction temperature is remarkable when Ga and Co are added simultaneously. On the contrary, Zr addition to $\text{Pr}_{13}\text{B}_6\text{Fe}_{\text{bal}}$ alloy may not cause the recombination reaction but make the disproportionation reaction sluggish. The Pr-Fe-B type magnet powder which has a remanence of 9.8 kG and coercivity of 4.8 kOe, was obtained by HDDR treatment. © 1998 American Institute of Physics. [S0021-8979(98)34611-3]

I. INTRODUCTION

Hydrogen treatment such as hydrogenation, disproportionation, desorption, and recombination (HDDR) process is now well established as a method of producing Nd-Fe-B type anisotropic magnetic powder through a hydrogen induced phase transformation.¹⁻⁴ The effects of such minor elements as Co, Ga, and Zr on the HDDR process of Nd-Fe-B type alloy have been intensively studied.⁵⁻⁷ However, the research on applying the HDDR treatment to Pr-Fe-B type alloy and HDDR phenomena with such additive elements in Pr-Fe-B type alloy were not available.

In Pr-Fe-B based alloys where Pr is used as the rare earth instead of Nd, $\text{Pr}_2\text{Fe}_{14}\text{B}$ compound may disproportionate into the mixture of PrH_2 , Fe_2B , and $\alpha\text{-Fe}$ at the disproportionation reaction stage of HDDR treatment. At the recombination reaction stage in HDDR treatment, these decomposed mixtures could be recombined into the fine grained $\text{Pr}_2\text{Fe}_{14}\text{B}$ phase. In the present study, the effects of such minor elements as Co, Ga, and Zr on the hydrogen absorption and desorption behavior of Pr-Fe-B type alloys were investigated focusing on the disproportionation and recombination reaction in HDDR process. In addition to this, magnetic properties of HDDR treated Pr-Fe-B type alloy were investigated.

II. EXPERIMENT

Pr-Fe-B alloy ingots of various composition were prepared by arc melting and induction melting weighed amounts of constituent elements. The alloy ingots were then homogenized at 1000 °C for 20 h in vacuum. After homogenization, alloy ingots were mechanically crushed down to powders of under 200 μm . These powders were used for investigating

the hydrogen absorption and desorption behavior. The chemical composition of alloys used in this study are shown in Table I.

For investigating the hydrogen absorption and desorption characteristics, the samples were heated from room temperature to 1000 °C at an initial hydrogen pressure of 760 Torr and then the pressure changes as well as temperature changes were monitored. At each measurement, an 8 g sample was used and the heating rate was 5 °C/min. The expansion of hydrogen at an elevated temperature was taken into account by performing blank test. The phase changes during hydrogen absorption and desorption were examined using a x-ray diffractometer with $\text{Cu-}k\alpha$ radiation.

The samples for HDDR treatment were prepared by hydrogen decrepitation at room temperature and subsequent milling. For HDDR treatment, the disproportionation treatment was carried out at 800 °C and subsequent evacuating was performed at 820 °C. The disproportionation time was varied. The bonded magnets were made by aligning and pressing after mixing the HDDR treated powders with solid phenol. This compacts were then cured at 120 °C for 2 h. The magnetic properties of bonded magnets were measured by a D.C Fluxmeter.

FIG. 1. The hydrogen absorption and desorption behavior in $\text{Pr}_{13}\text{B}_6\text{Fe}_{\text{bal.}}$ type alloys.

III. RESULT AND DISCUSSION

The pressure and the temperature changes in $\text{Pr}_{13}\text{B}_6\text{Fe}_{\text{bal.}}$ alloy, which is the standard composition in this study, on heating from room temperature to 1000 °C is shown in Fig. 1. The pressure change curve for this alloy consists of three regions, two hydrogen absorption regions (designated as a and c) and one hydrogen desorption region (designated as b). The first hydrogen absorption reaction of this alloy, which correspond to hydrogen absorption into Pr-rich and $\text{Pr}_2\text{Fe}_{14}\text{B}$ phases, starts at about 80 °C. This is followed by broad hydrogen desorption reaction. Another hydrogen absorption reaction corresponding to disproportionation reaction in HDDR process occurs at around 620 °C. The recombination reaction was not observed below 1000 °C in hydrogen atmosphere in Pr-Fe-B three component system. The two exothermic peaks on the temperature change curve correspond to the hydrogen absorption reaction.

Figure 2 shows the hydrogen absorption and desorption behavior of Co added Pr-Fe-B alloys. In order for investigation of effect of Co addition on the hydrogen absorption and desorption behavior, the contents of Co addition was varied from 6 to 24 at.%. The starting temperature of first

FIG. 2. The hydrogen absorption and desorption behavior in $\text{Pr}_{13}\text{B}_6\text{Co}_x\text{Fe}_{\text{bal.}}$ ($x=6, 12, 18, 24$) type alloys.

FIG. 3. X-ray diffraction pattern of powders after second hydrogen desorption reaction in $\text{Pr}_{13}\text{B}_6\text{Co}_{12}\text{Fe}_{\text{bal.}}$ type alloys.

hydrogen absorption reaction were varied 70 to 100 °C with the addition of Co. However, the occurring temperatures of second hydrogen absorption reaction corresponding to disproportionation reaction are almost the same as those in the alloys with or without Co, which is around 620 °C. So, the addition of Co to Pr-Fe-B type alloy may not affect the disproportionation reaction. On the contrary, in the alloy with Co content of 12 at.%, the second hydrogen desorption reaction (designated as d) occurs at 955 °C, which corresponds to the recombination reaction in HDDR process. The x-ray diffraction pattern of the powder after this desorption reaction in Fig. 3 shows that the diffraction peaks of $\text{Pr}_2\text{Fe}_{14}\text{B}$ phase, which were recombined from the decomposed mixture of PrH_2 , Fe_2B , and $\alpha\text{-Fe}$, are dominant. The second hydrogen desorption reaction in $\text{Pr}_{13}\text{B}_6\text{Co}_{18}\text{Fe}_{\text{bal.}}$ and $\text{Pr}_{13}\text{B}_6\text{Co}_{24}\text{Fe}_{\text{bal.}}$ alloys occurred at 940 and 925 °C, respectively. So, the occurring temperature of recombination reaction is further decreased with increasing Co content. The recombination reaction was not observed in the alloys with Co content below 6 at.%.

Figure 4 shows the hydrogen absorption and desorption behavior of Ga added Pr-Fe-B alloys. Ga was added from 0.5 to 1.5 at.%. The Ga addition to $\text{Pr}_{13}\text{B}_6\text{Fe}_{\text{bal.}}$ alloy also

FIG. 4. The hydrogen absorption and desorption behavior in $\text{Pr}_{13}\text{B}_6\text{Ga}_x\text{Fe}_{\text{bal.}}$ ($\text{Ga}=0.5, 1.5$) type alloys.

FIG. 5. The hydrogen absorption and desorption behavior in $\text{Pr}_{13}\text{B}_6\text{Co}_{12}(\text{Ga}_{1.5})\text{Fe}_{\text{bal.}}$ type alloys.

causes the recombination reaction below 1000 °C in hydrogen atmosphere, which is the same behavior as that observed in Co added alloys. In $\text{Pr}_{13}\text{B}_6\text{Ga}_{1.5}\text{Fe}_{\text{bal.}}$ the recombination reaction was occurred at about 940 °C, but small addition of Ga (0.5 at.%) does not cause the recombination reaction. The addition of Ga to $\text{Pr}_{13}\text{B}_6\text{Fe}_{\text{bal.}}$ has no significant influence on disproportionation reaction.

As shown in Fig. 2 and Fig. 4, the most distinct effects of Co and Ga addition to Pr-Fe-B system is the lowering of the recombination reaction temperature below 1000 °C in comparison with $\text{Pr}_{13}\text{B}_6\text{Fe}_{\text{bal.}}$ alloy. The decomposed mixture is considered to be less stable by the addition of Co and Ga and hence the recombination reaction starts at a lower temperature. This result indicates that the addition of Co and Ga to Pr-Fe-B alloy enhances the recombination reaction by lowering the recombination reaction temperature.

Figure 5 shows the hydrogen absorption and desorption behavior of $\text{Pr}_{13}\text{B}_6\text{Co}_{12}\text{Ga}_{1.5}\text{Fe}_{\text{bal.}}$ alloy. In this alloy, the recombination reaction starts at about 890 °C. In comparison with $\text{Pr}_{13}\text{B}_6\text{Co}_{12}\text{Fe}_{\text{bal.}}$, the starting temperature of recombination reaction was further decreased by Ga addition. The lowering of the occurring temperature is remarkable when Ga and Co are added simultaneously.

The hydrogen absorption and desorption behavior of Zr added Pr-Fe-B alloys is shown in Fig. 6. The Zr content was varied from 0.1 to 1.0 at. %. The shape of second hydrogen absorption curve corresponding to disproportionation reaction for alloy with 0.1 at. % Zr is broadened in comparison with $\text{Pr}_{13}\text{B}_6\text{Fe}_{\text{bal.}}$ alloy. This disproportionation curve is further broadened with increasing Zr content and both the starting and finishing temperature of disproportionation reaction were changed. So, it can be said that the addition of Zr to Pr-Fe-B alloy may retard the disproportionation reaction. In opposition to Co and Ga added Pr-Fe-B alloys, Zr addition to $\text{Pr}_{13}\text{B}_6\text{Fe}_{\text{bal.}}$ alloy does not cause the recombination reaction below 1000 °C in hydrogen atmosphere.

HDDR treatment was employed to the $\text{Pr}_{13}\text{B}_6\text{Zr}_{0.1}\text{Ga}_{1.0}\text{Co}_{24}\text{Fe}_{\text{bal.}}$ alloy. The samples for HDDR treatment were prepared by hydrogen decrepitation at room

FIG. 6. The hydrogen absorption and desorption behavior in $\text{Pr}_{13}\text{B}_6\text{Zr}_x\text{Fe}_{\text{bal.}}$ ($\text{Zr} = 0.1, 0.5, 1.0$) type alloys.

temperature and subsequent milling. HDDR treatment was carried out by keeping the sample at 800 °C in hydrogen and evacuating hydrogen from the sample at 820 °C. As a result, $\text{Pr}_{13}\text{B}_6\text{Zr}_{0.1}\text{Ga}_{1.0}\text{Co}_{24}\text{Fe}_{\text{bal.}}$ magnet powder having a remanence of 9.8 kG and a coercivity of 4.8 kOe was obtained by employing the HDDR treatment to Pr-Fe-B system.

IV. CONCLUSION

From the investigation of hydrogen absorption and desorption behavior of Pr-Fe-B type alloys and magnetic properties of HDDR treated Pr-Fe-B type magnetic powder, the following conclusions can be drawn.

The second hydrogen desorption reaction, which corresponds to recombination reaction in HDDR process, occurs at about 955 °C in $\text{Pr}_{13}\text{B}_6\text{Co}_{12}\text{Fe}_{\text{bal.}}$ alloy and the occurring temperature of recombination reaction is further decreased with increasing Co content. The Ga addition to $\text{Pr}_{13}\text{B}_6\text{Fe}_{\text{bal.}}$ alloy also reduces the recombination reaction temperature. So, the addition of Co and Ga to Pr-Fe-B alloy enhances the recombination reaction. Moreover, the lowering of the recombination reaction temperature is remarkable when Ga and Co are added simultaneously. The addition of Co and Ga to $\text{Pr}_{13}\text{B}_6\text{Fe}_{\text{bal.}}$ alloy has no significant influence on disproportionation reaction. On the contrary, Zr addition to $\text{Pr}_{13}\text{B}_6\text{Fe}_{\text{bal.}}$ alloy may not cause the recombination reaction but make the disproportionation reaction sluggish. The Pr-Fe-B type magnet powder which has a remanence of 9.8 kG and coercivity of 4.8 kOe, was obtained by HDDR treatment.

The temperature dependence of the coercive field of $\text{Nd}(\text{Fe}_{0.92-x}\text{Ga}_x\text{B}_{0.08})_{5.5}$ compounds with $x = 0$ and 0.01 has been measured from 10 K up to the Curie temperatures in fields applied parallel or perpendicular to the magnetic alignment direction and has been analyzed in terms of a micromagnetic model. Two temperature ranges in which different mechanisms control the coercivity can clearly be distinguished. At temperatures above 170 K , a nucleation process of reversed domains determines the coercivity mechanism. From the micromagnetism point of view, partial substitution of Fe by Ga into NdFeB magnets leads to a reduction of the local effective demagnetization field ($-N_{\text{eff}}M_s$) which makes the nucleation of reversed domains more difficult, and therefore enhances the coercivity. © 1998 American Institute of Physics.

[S0021-8979(98)15311-2]

Anisotropic NdFeB permanent magnets are mainly produced by the sintering technique.¹ The magnetic phase in NdFeB magnets is the tetragonal $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase which has exciting intrinsic magnetic properties. However, the coercive field realized in NdFeB magnets depends strongly on the microstructure. The main disadvantage of the NdFeB magnet is its large temperature coefficient of the coercivity. The way to reduce the temperature coefficient of a magnet is to increase either its coercive field or its Curie temperature. Partial substitution of Nd in NdFeB magnets by Tb and/or Dy results in a large enhancement of the coercive field. This is because of the huge uniaxial magnetic anisotropy of $\text{Tb}_2\text{Fe}_{14}\text{B}$ or $\text{Dy}_2\text{Fe}_{14}\text{B}$. However, substitution of Tb and/or Dy leads to a drastic reduction of the saturation magnetization. On the other hand, the Curie temperature of NdFeB magnets can be drastically increased by partial substitution of Fe by Co, however, at a cost of the coercive field. Ga is the only nonmagnetic element which simultaneously raises the Curie temperature² and the coercive field of NdFeB magnets. It is one of the main subjects of the present article to understand why the coercive field is enhanced in Ga-containing NdFeB magnets. In addition, the mechanism which controls the magnetization reversal process in NdFeB and $\text{Nd}(\text{Fe,Ga})\text{B}$ magnets will be studied with the main emphasis on the comparison of the temperature dependence of the coercive field measured with the field applied parallel and perpendicular to the magnetic-alignment direction.

Much effort was made to obtain magnets with a high degree of the grain alignment. A number of cylindrical samples with a diameter of 4 mm and a length of 6 mm were cut out from the bulk $\text{Nd}(\text{Fe}_{0.92}\text{B}_{0.08})_{5.5}$ and $\text{Nd}(\text{Fe}_{0.91}\text{Ga}_{0.01}\text{B}_{0.08})_{5.5}$ sintered magnets with the cylindrical axis parallel or perpendicular to the magnetic alignment direction. Magnetic hysteresis loops were measured from 10 to 800 K in a vibrating-sample magnetometer equipped with a

superconducting coil providing a maximum field strength of 6.4 MA/m . The value of the coercive field H_c is defined as the field where the irreversible susceptibility of the demagnetization curve has a maximum. According to this definition, the coercive field corresponds to the field where most domains reverse their magnetization direction under the action of the applied inverse field.

Figure 1 shows the magnetic hysteresis loops of $\text{Nd}(\text{Fe}_{0.91}\text{Ga}_{0.01}\text{B}_{0.08})_{5.5}$ measured at 300 K in external fields applied parallel and perpendicular to the magnetic-alignment direction. The presence of a fairly good grain alignment follows from the very pronounced difference of the magnetic hysteresis loops measured in the two directions. The hysteresis loop in the parallel measurements is predominantly due to magnetization reversal of the grains which are magnetically aligned. However, the hysteresis loop in the perpendicular measurements is only due to the presence of grains which are misaligned. This is because the magnetic moments of the aligned grains will be rotated to the direction of the applied field only when the external field exceeds the anisotropy field, which is about 7 MA/m at 300 K for $\text{Nd}_2\text{Fe}_{14}\text{B}$. According to the micromagnetic model of coercivity,^{3,4} the presence of misaligned grains in permanent magnets leads to lowering coercivity. This is because the nucleation field is lower in misaligned single-domain particles. From the present measurement, however, it becomes evident that the coercive field is larger when the magnetic hysteresis loop is measured in a perpendicular field. This experimental fact suggests the coercivity in misaligned grains to be larger than in perfectly aligned grains. It must be noted that it is a common feature of NdFeB sintered magnets that an improvement of the degree of grain alignment results in a reduction of the coercivity. To understand this seeming paradox between the experimental results and the theoretical prediction forms another main subject of the present article.

In Fig. 2, the temperature dependence of the coercive field of $\text{Nd}(\text{Fe}_{0.92}\text{B}_{0.08})_{5.5}$ and $\text{Nd}(\text{Fe}_{0.91}\text{Ga}_{0.01}\text{B}_{0.08})_{5.5}$ magnets is shown. It can be seen that the coercive fields mea-

FIG. 1. Magnetic hysteresis loops of $\text{Nd}(\text{Fe}_{0.91}\text{Ga}_{0.01}\text{B}_{0.08})_{5.5}$ sintered magnets measured in external fields applied parallel or perpendicular to the magnetic-alignment direction.

sured in a perpendicular field are higher at all temperatures where magnetic order exists. In the parallel measurements, compared to the pure NdFeB magnets, the Ga-containing magnets show a higher coercive field at higher temperature. In order to understand from the micromagnetic point of view why the coercive field changes upon Ga addition and why the perpendicular measurements give a higher coercive field, the intrinsic magnetic properties of $\text{Nd}_2\text{Fe}_{14}\text{B}$, e.g., the anisotropy constants, K_1 , K_2 , and the spontaneous magnetization M_s should be known. The values of K_1 , K_2 , and M_s of NdFeB magnets at various temperatures, corresponding to the measuring temperatures of H_c , were obtained by interpolating from the data of Hock,⁵ which have been obtained by measuring the magnetization of a $\text{Nd}_2\text{Fe}_{14}\text{B}$ single crystal.

Within the theory of micromagnetism, the coercive field H_c of a permanent magnet can be expressed as^{4,6}

$$H_c = \alpha_K \alpha_\phi H_n - N_{\text{eff}} M_s, \quad (1)$$

where H_n is the nucleation field of a spherical single-domain particle of a hard magnetic phase if the external field is applied exactly antiparallel to the magnetization vector. M_s is the spontaneous magnetization of the hard magnetic phase. α_K , α_ϕ , and N_{eff} are micromagnetic parameters which describe the deviation of the coercivity in real magnets from

FIG. 2. Temperature dependence of the coercive field H_c of $\text{Nd}(\text{Fe}_{0.92}\text{B}_{0.08})_{5.5}$ and $\text{Nd}(\text{Fe}_{0.91}\text{Ga}_{0.01}\text{B}_{0.08})_{5.5}$ sintered magnets.

FIG. 3. Least-square linear fit of the H_c/M_s vs H_n^{min}/M_s curves of $\text{Nd}(\text{Fe}_{0.92}\text{B}_{0.08})_{5.5}$ in two temperature ranges. The H_c values were obtained from magnetic hysteresis loops measured in a field parallel to the magnetic-alignment direction.

the nucleation field in a spherical single-domain particle. α_K is the parameter which describes the reduction of the nucleation field caused by the low magnetic anisotropy at the grain surface. α_ϕ represents the reduction of the nucleation field due to the presence of the misaligned grains. This is because the misaligned single-domain particles have a low nucleation field and the nucleated reversed domains in the grains should have the same easy magnetization direction (EMD) as the grains themselves. Theoretically, both α_ϕ and α_K are temperature dependent. The micromagnetic parameter, N_{eff} , determines the locations where the reversed domains are preferentially nucleated.

FIG. 4. Least-square linear fit of the H_c/M_s vs H_n^{min}/M_s curves for $\text{Nd}(\text{Fe}_{0.91}\text{Ga}_{0.01}\text{B}_{0.08})_{5.5}$ magnets at two temperature ranges. The H_c values were obtained from magnetic hysteresis loops measured in a field parallel to the magnetic-alignment direction.

FIG. 5. Least-square linear fit of the H_c/M_s vs H_n^{\min}/M_s curves for $\text{Nd}(\text{Fe}_{0.91}\text{Ga}_{0.01}\text{B}_{0.08})_{5.5}$ magnets at two temperature ranges. The H_c values were obtained from magnetic hysteresis loops measured in a field perpendicular to the magnetic-alignment direction.

The value of the nucleation field, H_n , is determined only by the intrinsic magnetic properties of the hard-magnetic phase, i.e., of $\text{Nd}_2\text{Fe}_{14}\text{B}$. From the data on the anisotropy constants obtained by Hock,⁵ it follows that at temperatures above 170 K the conditions $K_1 \gg K_2$ and $K_1 \neq 0$ hold. The nucleation field H_n and the parameter α_φ can be calculated by means of the expressions:

$$H_n^1 = \frac{2K_1}{\mu_0 M_s}$$

and

$$\alpha_\varphi = \frac{1}{\cos \varphi} \frac{1}{(1 + \tan^{2/3} \varphi)^{3/2}} \left(1 + \frac{2K_2}{K_1} \frac{\tan^{2/3} \varphi}{1 + \tan^{2/3} \varphi} \right),$$

where φ is the angle between the EMD of the grain and the direction of the applied magnetic field. At temperatures below 170 K, the condition $-2K_2 < K_1 < 4K_2$ holds. In this case, α_φ can only be obtained by numerical calculation. The minimum of H_n^{II} has been calculated by Martinek *et al.*⁷ to be:

$$H_n^{\text{II min}} = \frac{1}{\mu_0 M_s} \frac{1}{2\sqrt{2}} \left[K_1 + \frac{K_2}{4} \left(W - \frac{K_1}{K_2} + 3 \right) \right] \\ \times \sqrt{\left[W \left(\frac{K_1}{K_2} + 1 \right) - \left(\frac{K_1}{K_2} \right)^2 - \frac{2K_1}{K_2} + 3 \right]},$$

where

$$W = \sqrt{\left(\frac{K_1}{K_2} + 1 \right)^2 + 8}.$$

In a real magnet, misalignment is inevitable and a distribution of the grain alignment exists. The nucleation field differs therefore from one grain to the other. For simplicity,

it is assumed that the coercive field of the bulk magnet is determined by the grains which have the minimum nucleation field ($H_n^{\min} = \alpha_\varphi^{\min} H_n$).

In Fig. 3, H_c/M_s is plotted as the function of H_n^{\min}/M_s for $\text{Nd}(\text{Fe}_{0.92}\text{B}_{0.08})_{5.5}$ permanent magnets. Similar to what was found previously,⁸ two clearly distinguishable temperature ranges can be seen. At temperatures above 170 K, H_n^{I} is the nucleation field, whereas H_n^{II} is the nucleation field below 170 K. The mechanism which controls the coercivity may be different in these two temperature ranges. A least-square linear fitting program was applied to fit separately the H_c/M_s vs H_n^{\min}/M_s curves in two temperature ranges. The fitting parameters, α_K and N_{eff} , are included in the figure. A large difference in values of N_{eff} is evident in these two temperature ranges. In the temperature range where H_n^{I} is the nucleation field, the value of N_{eff} is rather large. This implies that the magnetization reversal process in this temperature range is realized through expansion of reversed domains which are nucleated preferentially in the region of the grain surface where the local effective demagnetizing field ($-N_{\text{eff}}M_s$) is the largest. On the other hand, in the temperature range where H_n^{II} is the nucleation field, the value of N_{eff} is rather small or even negative. This suggests that reversed domains in this temperature range are not nucleated due to a large local effective demagnetizing field. In the present analysis, the main emphasis will be on the temperatures above 170 K.

In Figs. 4 and 5, plots of H_c/M_s vs H_n^{\min}/M_s are shown for measurements parallel and perpendicular to the magnetic-alignment direction, respectively. Similar to what was found for $\text{Nd}(\text{Fe}_{0.92}\text{B}_{0.08})_{5.5}$, there are two temperature ranges which manifest themselves by different mechanisms in the magnetization reversal process. Let us first compare the results in the temperature range above 170 K, as shown in Figs. 3 and 4, which should reveal the influence of the Ga additive. Compared to the $\text{Nd}(\text{Fe}_{0.92}\text{B}_{0.08})_{5.5}$ magnet, the $\text{Nd}(\text{Fe}_{0.91}\text{Ga}_{0.01}\text{B}_{0.08})_{5.5}$ magnet has a lower value of α_K and a much lower value of N_{eff} . The low value of α_K leads to a reduction of coercivity, whereas the low value of N_{eff} results in a large coercivity. This result suggests that the enhancement of the coercivity in $\text{Nd}(\text{Fe}_{0.91}\text{Ga}_{0.01}\text{B}_{0.08})_{5.5}$ is mainly due to the reduction of the local effective demagnetization field ($-N_{\text{eff}}M_s$). A similar conclusion can be drawn from a comparison of Figs. 4 and 5. The misaligned grains have a lower nucleation field which reduces the coercivity. On the other hand, the much lower local effective demagnetization field drastically enhances the coercivity.

The origin and interpretation of fine scale magnetic contrast in magnetic force microscopy: A study using single-crystal NdFeB and a range of magnetic force microscopy tips

M. Al-Khafaji,^{a)} W. M. Rainforth,^{a)} M. R. J. Gibbs,^{b),c)} J. E. L. Bishop,^{b)} and H. A. Davies^{a)}
Sheffield Centre for Advanced Magnetic Materials and Devices, Sheffield, United Kingdom

We have used an oriented single crystal of Nd₂Fe₁₄B₁ as a test sample to explore contrast and resolution as a function of magnetic force microscopy tip coating, tip scan height, and sample history. We find that resolution is independent of tip type; that contrast is greater at low scan heights and for higher moment tips; and that the fine length scale structure of order 25 nm can be resolved. We further show how the surface structure is a function of state (demagnetized or remanent), demonstrating the ability of well-characterized studies to give high-resolution information on carefully prepared samples. © 1998 American Institute of Physics. [S0021-8979(98)16611-2]

INTRODUCTION

In magnetic force microscopy (MFM) the interaction between the tip magnetic moment and the stray field gradient (SFG) above a sample raises a number of issues. The SFG includes contributions from surface and subsurface domain structure, and surface topology. The response of the tip depends on the magnetization process within the tip, on the local SFG (dominated by contributions from local structure), and also, depending on the tip susceptibility, on the magnitude and direction of the field itself. While the SFG is strongly dominated by local contributions, the field will include significant long-range contributions, and indeed, may strongly reflect the gross magnetic state of the tip. A fully quantitative interpretation of the MFM signal must remain a distant goal.

Systematic observations, with sufficiently close control of the variables, are required in order to establish MFM performance. Convention has it that the spatial resolution limit is the tip-sample spacing or the tip radius, whichever is the greater. We have previously reported¹ fine scale magnetic-force gradient contrast in MFM images taken on a plane orthogonal to the easy axis of a large single crystal of as-grown Nd₂Fe₁₄B, having high *c*-axis texture. This single-crystal sample constitutes a stable test sample, with a large area for scanning, and high coercivity and high anisotropy energy. Magnetic contrast was clearly observed on a scale of order 25 nm, less than the tip-sample spacing and of the order of the tip radius. We now extend this study in three ways: we explore the resolution limit; the image formation for different tip coatings; and the NdFeB sample in a number of magnetic states.

EXPERIMENTAL DETAILS

A Digital Instruments Dimension 3000 scanning probe microscope was used in the Tapping/Lift™ mode, using sili-

con cantilevers with integral pyramidal tips and commercial coatings (Digital Instruments) of CoCr (high coercivity) and NiFe (low coercivity).²

THE RESOLUTION LIMIT

Figure 1 shows MFM images of the NdFeB single crystal (as-grown) using a NiFe coated tip. Registration of the images (gross features are the same on all images) was maintained using features in the associated topographic scan (not shown). A remarkable feature of the 25 nm scale fine structure is a distinct pattern of fine curved lines that repetitively decorate the bends of the rick-rack domain pattern. The con-

FIG. 2. $7\text{ }\mu\text{m}\times 7\text{ }\mu\text{m}$ MFM images from the surface of an as-grown NdFeB single crystal on a face orthogonal to the easy axis. Scan heights (a) 100 nm and (b) 200 nm. Tip CoCr. Contrast=phase shift of 60° .

trast and resolution vary with scan height, but gross features are maintained. Analysis shows that the image is influenced primarily by features near the surface to a depth proportional to the scan height. Thus, increasing the scan height does not simply blur the details, but enhances the relative sensitivity to deeper structures. Scanning with a second NiFe tip produced identical results.

Figure 2 shows analogous images for a CoCr coated tip from another area of the sample, again in register for the series. As for the NiFe tip, the gross features are reproduced, only the contrast and resolution decrease with increasing scan height.

Of particular significance is the fine scale structure observed in both of the low scan height images, including the repetitive pattern discussed above. The resolution limit is practically tip independent, and also scanning in an orthogonal direction produces an essentially identical image. It must be deduced that the simple rule for the resolution limit given in the Introduction is not adequate, and that many finer scale features can be reproducibly observed.

COMPARISON OF TIP COATINGS

According to earlier studies² on such tips, the magnetic characteristics should be very different, the CoCr presenting a high moment, high coercivity behavior, while the NiFe is lower moment and lower coercivity. Comparing images between tips for the same scan height, it is clear that the resolution is largely independent of tip character.

A simple comparison of Figs. 1 and 2 demonstrates that the nature of the contrast is, as expected, somewhat different

FIG. 3. MFM images orthogonal to the c axis of a thermally demagnetized single crystal of $\text{Nd}_2\text{Fe}_{14}\text{B}$. CoCr tip. (a) $35\times 35\text{ }\mu\text{m}$:100 nm scan height and (b) $5\times 5\text{ }\mu\text{m}$:100 nm scan height. Black-white contrast= 50° phase shift.

for the two tip coatings. This can be interpreted in terms of the CoCr tip behaving essentially as a fixed dipole, whereas the moment of the NiFe is controlled by the field of the Nd-Fe-B. Thus, the CoCr tip primarily delineates the domains, while the NiFe tip primarily delineates the domain walls.³ It is important to emphasize that the fine scale structure is visible with both tips, that is, it must reflect the underlying magnetic domain structure and is, therefore, no artifact.

STUDY OF NdFeB SINGLE CRYSTAL IN DIFFERENT MAGNETIC STATES

Two distinct types of features are visible in Fig. 3 (a thermally demagnetized state); closure spike domains (bright spots dispersed across the image),⁴ and rick-rack domains.¹ The fine scale line structure associated with the rick-rack pattern is again observed, with the rick-rack domains parallel to each other over distances long compared to their separation and wavelength. For the remanent state after magnetization to 5 T in a hard direction (Fig. 4), this long-range structure is not present, the rick-rack pattern has become much more convoluted, and the incidence of spike domains has decreased. There is now an absence of the fine line structure associated with the rick-rack pattern.

For the remanent state after magnetization to 5 T in the easy direction (Fig. 5), the convolution of the rick-rack pattern is similar to the other remanent state. The incidence of spike domains remains low, but the fine line structure associated with the rick-rack domains is more pronounced.

FIG. 4. MFM images orthogonal to the c axis of a single crystal of $\text{Nd}_2\text{Fe}_{14}\text{B}$, in a remanent state after magnetization to 5 T with the field in the sample plane. CoCr tip. (a) $35 \times 35 \mu\text{m}$ at 100 nm scan height and (b) $5 \times 5 \mu\text{m}$ at 100 nm scan height. Black-white contrast $\equiv 50^\circ$ phase shift.

From these detailed comparisons it is possible to conclude that the rick-rack pattern represents a closure structure on the surface of a sample of high uniaxial anisotropy constant $K_1 > 2\pi M_s^2$.¹ The gross features of this pattern are unaffected by previous magnetic history, except in the case of thermal demagnetization. Figure 3(a) demonstrates that the convolution is much less after demagnetization. A reasonable interpretation is that in achieving the thermally demagnetized state, the fundamental underlying domain structure is more ordered and less complex. The long-range quasiparallel orientation of the rick-rack walls suggests the underlying structure approximates the well-known stripe domain structure.

The fine scale line structure parasitic on the rick-rack pattern is clearly influenced by the magnetic history. In the case of Fig. 4 where a field of 5 T has been applied and then removed in plane, this fine detail is not evident. This suggests that in these regions, close to the sample surface, further energy minimization is possible, when the remanent state is along the easy direction (Fig. 5), by division into

FIG. 5. MFM as in Fig. 4 in a remanent state after magnetization to 5 T with the field orthogonal to the sample plane. CoCr tip. (a) $35 \times 35 \mu\text{m}$ at 100 nm scan height and (b) $5 \times 5 \mu\text{m}$ at 100 nm scan height. Black-white contrast $\equiv 50^\circ$ phase shift.

smaller closure domains at regions of high wall curvature. It is certainly also true that this fine scale contrast is magnetic in origin, although the length scale is so short.

CONCLUSIONS

The fine scale structure on a scale of 25 nm, much less than the tip-sample spacing, and of the order of the tip radius, is clearly resolved and of magnetic origin. Its existence is independent of tip materials. It is seen in thermally demagnetized samples and in samples remanent after magnetization in the easy direction normal to the surface, but not when the remanent state is reached after magnetization in a hard direction.

Off-axis electron holographic mapping of magnetic domains in $\text{Nd}_2\text{Fe}_{14}\text{B}$

M. R. McCartney

Yimei Zhu

Department of Applied Sciences, Brookhaven National Laboratory, Upton, New York 11973

Off-axis electron holography employing a field-free Lorentz lens has been used to provide direct imaging of magnetic induction in $\text{Nd}_2\text{Fe}_{14}\text{B}$ with nanometer-scale resolution and high signal-to-noise. Using this technique, reconstructed phase images have been used to measure domain wall widths for 90° and 180° walls in a sintered sample were measured to be no greater than 7 and 9 nm, respectively. Induction maps show an unusual array of 90° domains in a hot-press sample, with singularities at the intersections of the domains. *In situ* thermal annealing of the hot-pressed sample resulted in magnetization rotation accompanied by domain wall movement and evidence for pinning at a structural defect. Heating of the sample above 400°C resulted in the accumulation of small particles in thin regions and decrease in magnetic contrast. © 1998 American Institute of Physics. [S0021-8979(98)41411-7]

Hard magnetic materials such as NdFeB alloys have high remanence and coercivity that potentially lead to many practical applications.^{1,2} Magnetic force microscopy (MFM) and scanning electron microscopy with polarization analysis (SEMPA)³ can provide quantitative information about surface features such as domain walls that intersect the surface of bulk magnetic materials. Transmission electron microscopy techniques for imaging thin magnetic films include Foucault imaging⁴ and differential phase contrast⁵ imaging which give direction-dependent magnetization contrast, and out-of-focus, Fresnel or Lorentz imaging which gives contrast at domain wall positions.⁶ Off-axis electron holography is a technique that is sensitive to electrostatic and magnetic potentials within solid materials. In particular, the magnetic induction strength and direction can be imaged at high resolution and with high sensitivity.⁷ In this work, we describe the use of off-axis electron holography to map the induction distribution of magnetic domains in $\text{Nd}_2\text{Fe}_{14}\text{B}$ alloys at nanoscale spatial resolution.

The electron holograms and Lorentz images were recorded with a Philips CM200 transmission electron microscope equipped with a field emission electron source.⁸ This instrument has a (Lorentz) mini-lens in the region below the lower objective polepiece which provides a line resolution of 1.2 nm with only a small residual field at the sample. The microscope is equipped with an electrostatic biprism in the plane of the selected area aperture holder for off-axis electron holography. Holograms and Fresnel images were recorded digitally with a Gatan 679 slow-scan CCD camera. A double-tilt heating holder was used to investigate the effects of heating cycles on the induction distribution.

A pair of Fresnel images from a sintered sample of $\text{Nd}_2\text{Fe}_{14}\text{B}$ recorded under field-free conditions are shown in Figs. 1(a) and 1(b). The contrast at the domain walls (arrowed) has inverted upon going from underfocus to overfocus. Figure 1(c) shows a contoured phase image that was reconstructed from an off-axis electron hologram of the indicated region of Fig. 1(a). The equispaced contours within each domain indicate uniform magnetization that gives rise

to a constant phase plane. The normal to this plane is related to the direction and magnitude of the induction. Ridges and valleys in the phase image can be directly related to the bright and dark lines in the underfocus Fresnel image. These abrupt changes in slope are associated with changing magnetization and correspond to the domain wall positions. In order to map the magnetic induction within the sample, simple gradients of the phase image can be calculated by displacing the phase image, followed by subtraction.⁹ Figure 1(d) shows the vertical gradient of the phase and reveals the horizontal component of the induction.

Two perpendicular gradient images can be combined into a vector map to produce a direct image of magnetic structure within the domains, as shown in Fig. 2(a). The vector map is divided into $10\text{ nm} \times 10\text{ nm}$ squares, and shows three distinct domains with the top and middle domains ori-

FIG. 2. (a) Induction map derived from phase gradients in Fig. 1 with 90° and 180° domain walls. (b) Domain wall width measurements from phase profiles. Circles (top wall) and squares (bottom wall) are phase data, solid lines are linear fits.

ented at approximately 90° and the middle and lower oriented at approximately 180° to each other. The minimum vector length indicates out-of-plane or vanishing induction. The vectors which delineate the edge of the sample are an artefact due to the rapid increase in mean potential at the sample-vacuum interface. Within the sample, the vector length corresponds to the product of the in-plane magnetization and the thickness. Using an estimate of 60 nm for the thickness^{10,11} for thicker areas of the sample (on the left of Fig. 2), the vector lengths calculated from the modulus of the gradients correspond to magnetizations, $4\pi M_s = B = 0.8$ T, 1.2 T, and 0.5 T for the top, middle, and bottom domains, respectively. Care should be taken when interpreting details of the induction maps, particularly because of undetermined fringing fields immediately above and below the sample surface. For example, such demagnetizing fields, visible as curved contour lines extending into vacuum at the lower right of Fig. 1(c) may be responsible for the apparent reduction of the magnetization in the bottom domain. In addition, it should be noted that the technique is only sensitive to the in-plane component so that any crystal tilt toward the c -axis normal will reduce the measured magnetization.

An estimate for domain wall width can be made directly from the phase image by measuring the distance over which the phase slope abruptly changes. Figure 2(b) shows phase profiles taken perpendicular to the top (90°) and bottom (180°) domain walls. The open circles (squares) are the

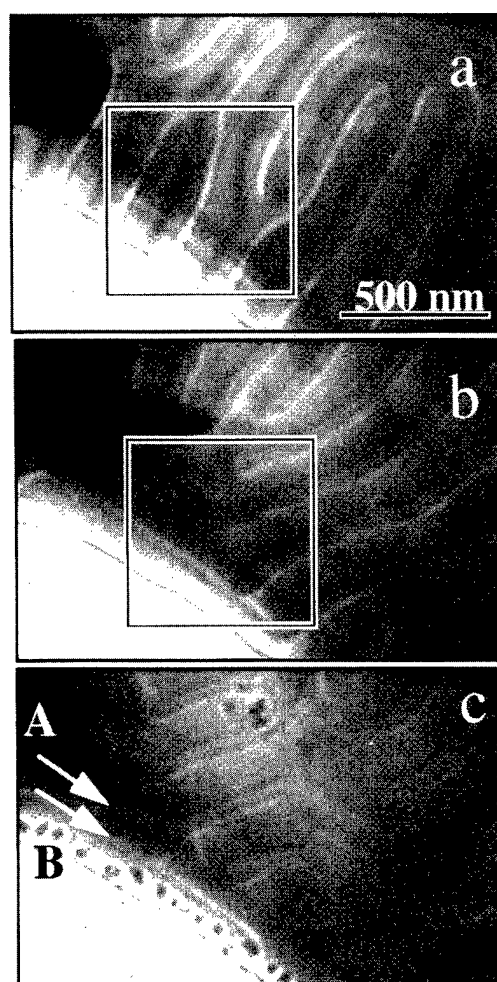

FIG. 3. Fresnel under-focus images of die-upset $\text{Nd}_2\text{Fe}_2\text{B}$ as function of temperature: (a) room temperature; (b) heated to 300°C and then cooled to room temperature; (c) heated above the Curie temperature, then cooled. "A" indicates domain wall associated with crystal defect, "B" is a grain boundary.

phase data averaged over 20 nm and the solid lines are least square linear fits to the data. These measurements indicate a maximum¹² width of 6.7 ± 1.4 nm and 9.2 ± 1.4 nm for the upper and lower domain walls, respectively.

Under-focus Lorentz images of a sample of die-upset¹³ $\text{Nd}_2\text{Fe}_{14}\text{B}$ are shown in Fig. 3. The characteristic lines of light and dark contrast in Fig. 3(a) correspond to serpentine and "Y"-shaped domains that extend to the sample edge. The shape of these domains is similar to that previously reported near grain boundaries in sintered Nd-Fe-B .¹⁴ In addition, two features are noted, one dark and one bright, which are labeled "A" and "B," that lie parallel to the vacuum edge and intersect the domains which form the stems of the Y domains. Analysis of these features, reported elsewhere, indicates that feature A is associated with an unidentified planar defect while B is a grain boundary.⁹

Domain rearrangement resulted from heating the sample *in situ* to a nominal 300°C followed by cooling to room temperature, as shown in Fig. 3(b). The domain walls have been released from the thin sample edge although some domains still interact with features A and B. Subsequent heat-

FIG. 4. Induction map from outlined areas of Fig. 3 showing change in domain structure before (a) and after (b) heating to 300 °C.

ing to 400°C (above the Curie temperature of 585 K¹⁵) resulted in complete disappearance of the domain structure. A new domain structure was then visible after cooling to room temperature, as shown in Fig. 3(c). The domain boundaries again interact with features A and B but none of the domain walls extend to the thin edge of the annealed sample. The sample has accumulated dark particles in areas near the edge and on the surface of thinner parts of the specimen. The presence of the particles is correlated to an absence of domain walls and a marked reduction in the Fresnel contrast of the domain walls in the interior of the sample.

Electron holograms were recorded at various stages of this treatment cycle, and then later processed to obtain phase and phase gradient images. The vector map shown in Fig. 4(a), which has been superimposed on a low contrast image of the x gradient, is divided into 20 nm×20 nm squares. The map shows that the magnetizations of the domains in this region of the sample are oriented at approximately 90° to each other rather than the expected 180°. The region of the sample between A and the vacuum edge is comprised of a series of domains which appear to close the in-plane induction more or less parallel to the thin edge, and give rise to

pairs of singularities at the intersection with the striped domains. This structure is reminiscent of cross-tie walls that contain periodic arrays of Bloch lines of alternating polarity.^{7,16} The grain boundary has a limited effect on the magnetization, and the magnetization across the two grains is coupled. Effects at the grain boundary itself may arise not only from changes in the induction but also from preferential thinning or changes in composition at the boundary. Between this grain boundary and the sample edge, the vectors show decreasing length which may be due to rapidly decreasing specimen thickness rather than an increased out-of-plane component.

Figure 4(b) is an induction map of the same area [see Fig. 1(b)] after heating to 300° and subsequent cooling to room temperature. The well-defined domains on the left-hand side have disappeared, and the reduced phase gradients may indicate that the remaining structure has a large out-of-plane component. The domains which had previously been oriented perpendicular to the edge of the sample have rotated by approximately 90° and the magnetizations of adjacent domains are now oriented at approximately 180°. The magnetizations on either side of the grain boundary are no longer strongly coupled. However, the domains in the lower part of the figure appear to be pinned between the grain boundary and the defect which have impeded the movement of domains away from the thin edge of the sample and preserved the original orientation.

Improvement of protective coating on Nd-Fe-B magnet by pulse nickel plating

C. W. Cheng and F. T. Cheng^{a)}

Department of Applied Physics, The Hong Kong Polytechnic University, Hung Hom, Hong Kong

H. C. Man

Department of Manufacturing Engineering, The Hong Kong Polytechnic University, Hung Hom, Hong Kong

Sintered Nd-Fe-B magnets were coated by pulse nickel plating at different plating conditions. Optimal pulse plating condition was established (average current density = 1 A/dm², peak current density = 6 A/dm² with $T_{\text{on}}:T_{\text{off}} = 1:2$). In order to make a comparison, magnets with similar nickel coating thickness plated by dc were also prepared. The corrosion resistance of the coated magnets was evaluated by (i) Normal Salt Spray Test (5% NaCl, 35 °C) and (ii) potentiodynamic polarization measurement (3.5% NaCl solution). It was found that the corrosion resistance of the pulse nickel plated magnet was significantly improved as compared with that of the conventional dc plated ones, with negligible deterioration in magnetism. The microstructure of the coating was examined by optical microscopy and scanning electron microscopy. It was found that the porosity was much lower, and the grains much finer in the pulse-plated layer as compared with the dc plated ones.

I. INTRODUCTION

The neodymium-iron-boron (Nd-Fe-B) permanent magnet, being one of the most popular magnets nowadays, derives its attractiveness and popularity from its well known excellent magnetic properties, including high remanence, high coercivity, and large energy product.¹ However, the applications of the Nd-Fe-B magnets are greatly hindered by their poor corrosion resistance in humid environments, especially when the magnets are of the sintered type.² The corrosion attack arises from the preferential oxidation of the Nd-rich phase in the grain boundary region.³ Such an intergranular mode of corrosion results in irreversible loss in flux and coercivity,⁴ contamination, and even total disintegration. The employment of coatings on the Nd-Fe-B magnets has been proven to be one feasible way to enhance the corrosion resistance without leading to significant deterioration of the magnetic properties. Among the various types of coatings applied to the Nd-Fe-B magnets, metallic coatings of Ni, Ni/Cr, Al, Zn, Cu, etc., have achieved different degrees of corrosion protection.⁵⁻⁹ Such metallic coatings were applied to Nd-Fe-B by dc electroplating, electroless plating, or immersion coating. On the other hand pulse plating, a technique which is well known for producing coatings which are more uniform, less porous, more wear-resistant and more corrosion-resistant (although with higher equipment cost, about twice that of the dc ones), has not been used on the Nd-Fe-B magnets. Thus it is the purpose of the present study to investigate the possibility of pulse plating the Nd-Fe-B magnets with Ni, to establish the optimal plating conditions, and to assess the coating properties.

II. EXPERIMENTAL PROCEDURE

Commercial Nd-Fe-B magnets composed of 15% Nd, 77% Fe, and 8% B were used in the present study. They

were in disk form with diameter and thickness of 15.7 and 2.2 mm, respectively. The samples were fabricated by conventional sintering and supplied by a local manufacturer. The magnetic properties were given as $B_r = 11.4$ kG, $H_{ci} = 12.4$ kOe, and $(BH)_{\text{max}} = 34$ MGOe.

The samples were cleaned by electrodegreasing in an alkaline solution, and then immersed in 10% hydrochloric acid at room temperature for 30 s for activation. The samples were pretreated with Ni striking at a current density of 2 A/dm² for 1 min, followed by dc plating of semi-bright Ni at 50 °C for 5 min using 1 A/dm². The samples were subsequently pulse plated with Ni using unipolar pulse in a bath having the composition and conditions listed in Table I. Four selected combinations of on and off times ($T_{\text{on}}:T_{\text{off}} = 1:1, 1:2, 1:4, 1:10$) were prepared. The mean thickness of the Ni coating film was in the range of 12–15 μm. For comparison, dc plated Ni coatings of similar thickness were also prepared using similar current densities.

The corrosion resistance of Ni coatings was investigated by (i) normal salt spray (NSS) test and (ii) electrochemical measurement. The NSS test (35 °C, 5% NaCl) was performed for 136 h using a standard chamber in accordance with ASTM G85 practice.

FIG. 1. Cross section of pulse Ni-plated samples (a) with pretreatment, (b) without pretreatment.

The time of initial formation of brown rust on the samples was recorded. Samples were removed at regular intervals from the chamber, carefully cleaned with de-ionized water, and dried thoroughly with warm air and weighed. The mass gain per unit surface area exposed due to the formation of corrosion product was also recorded and plotted against the exposure time.

In the electrochemical measurement of the samples, an EG&G PARC 273 potentiostat was used to obtain the potentiodynamic polarization scans. Two parallel graphite rods were used as the counter electrode and the saturated calomel electrode (SCE) was used as the reference electrode. Potentiodynamic polarization scans were carried out according to ASTM G5 practice, using deaerated 3.5% NaCl solution as the electrolyte at a scan rate of 0.6 V/h, scanning from -1 to $+1.2$ V. The corrosion potential E_{corr} and the corrosion current density i_{corr} were determined from the polarization curves using Tafel extrapolation.

Magnetic measurements were performed after 136 h of exposure in the salt spray test. The samples were pulse magnetized in a field of 35 kOe and demagnetized in a vibrating sample magnetometer (VSM) to obtain the demagnetization curves. The remanence B_r and the coercivity H_{ci} were determined.

FIG. 2. Surfaces of samples before and after 16 h of exposure in salt spray test: dc-plated (a)(c); pulse-plated (b)(d). (3.5X).

TABLE II. Time of initial formation of brown rust in NSS test for different settings.

Plating technique	T_{on} (μs)	T_{off} (μs)	Time of initial formation of brown rust (h)
Pulse-plated	200	200	15
	200	400	16
	200	800	8
	200	2000	10
dc-plated	8

III. RESULTS AND DISCUSSION

Pulse Ni coating having a thickness of 12–15 μm was obtained and the cross section is shown in Fig. 1(a). The coating was smooth and good adhesion was observed between the substrate and the coating. Pretreatment using dc plated semi-bright Ni was found to have greatly improved the adhesion of the coating to the substrate. The pretreatment prevented direct attack of the acidic bath on the magnet surface and hence prevented disintegration of the grains at the interlayer. Figure 1(b) revealed voids and pores appearing between the substrate and the coating without pretreatment. To achieve a high quality coating at a reasonable deposition rate, proper selection of current density is of primary importance. In the present study the optimal average current density was 1 A/dm² at 50 °C, with a peak current density of 6 A/dm². An on time of 200 μs was employed since it is the most common selection for ferrous material with a reasonable deposition rate.

The corrosion resistance of four different pulse-plated Ni coatings, together with dc-plated Ni coating and the bare sample was assessed in the salt spray environment. The surfaces of dc-plated and pulse-plated samples before and after 16 h of salt spray test are shown in Fig. 2. It could be seen that the dc coating was seriously damaged [Fig. 2(c)] while for the pulse coating, the corrosion product just began to form [Fig. 2(d)]. The time of initial formation of brown rust was recorded and listed in Table II. It was found that the initial time for rust formation in pulse-plated samples was retarded by a factor of 2 as compared with that for the dc

FIG. 3. Mass gain per unit sample area exposed at different exposure times in NSS test.

TABLE III. E_{corr} and i_{corr} from potentiodynamic polarization measurement of different plated samples.

Samples	E_{corr} (mV)	i_{corr} ($\mu\text{A}/\text{cm}^2$)
Pulse-plated Ni ($T_{\text{on}}:T_{\text{off}}=1:2$)	-440	0.12
dc plated Ni	-530	0.98
Uncoated Nd-Fe-B	-940.7	115.7

plated samples, extending up to 16 h for coatings with an on-off time ratio of 1:2. For bare samples, corrosion products were visible after 2 h of exposure.

The mass gain due to the formation of rust at different times of exposure is shown in Fig. 3. It was found that the mass increased at a faster rate after initial formation of rust, indicating breakdown of coating and exposure of the substrate to the salt mist environment.

Potentiodynamic polarization test of the pulse Ni-plated, dc Ni-plated and the bare samples in 3.5% NaCl deaerated solution at room temperature was performed and the corresponding corrosion potential E_{corr} and the corrosion current density i_{corr} were listed in Table III. The i_{corr} of the bare Nd-Fe-B was much greater than those of the coated ones, in fact greater by a few orders of magnitude. The i_{corr} of the pulse-plated samples was lower than that of the dc-plated samples by about an order of magnitude. The reduction in corrosion rate is probably due to the removal of discontinuities and pores which are usually present in dc plating. The more noble value of E_{corr} for pulse Ni coating indicated that the coating was more stable as compared with that of the conventional dc plating. Thus both the salt spray test and electrochemical test showed that the pulse-plated samples were more corrosion resistant than the dc plated ones. The improvement in corrosion resistance may be attributed to the structure of the coating in pulse plating, which is characterized by finer grains and lower porosity, as shown in Fig. 4(a)

FIG. 4. Scanning electron microscope (SEM) micrographs of surfaces of pulse-plated (a) and dc-plated (b) samples.

TABLE IV. Magnetic properties before and after salt spray test.

	Before NSS test		After NSS test		Loss in B_r (%)
	B_r (kG)	H_{cl} (kOe)	B_r (kG)	H_{cl} (kOe)	
Pulse-plated Ni	11.3	12.4	11.2	12.3	0.88%
dc-plated Ni	11.3	12.3	11.1	12.3	1.77%
Uncoated	11.6	12.3	10.9	12.2	6.51%

versus the case of dc plating, Fig. 4(b).¹⁰

After 136 h of exposure in the salt spray test, the magnetic properties of the coated samples remained almost unchanged, whereas those of the bare samples decreased by about 6.5% (Table IV).

IV. CONCLUSIONS

Ni coating of thickness 12–15 μm has been successfully applied to the magnets by pulse plating. The set of conditions used was: average current density = 1 A/dm², peak value = 6 A/dm², temperature = 50°C, on-off times = 200 μs :400 μs . The coating obtained was fine-grained and low in porosity, and adhered well to the substrate. Corrosion data from both the salt spray test and electrochemical test indicated that for similar coating thickness, the corrosion resistance of the pulse Ni-plated samples was at least doubled as compared with the dc-plated ones. Magnetic measurements revealed that the remanence and the coercivity of the magnets were unaffected by the Ni coating.

A pump with flat-ring-shaped magnets

H. Saotome,^{a)} T. Hagiwara, and Y. Sato

Faculty of Engineering, Chiba University, Inage, Chiba 263, Japan

Previously, authors developed a novel linear actuator with flat-ring-shaped magnets and applied it to a pump. In this article, the output power of the actuator and the efficiency of the pump are obtained by experiments. A pair of flat-ring-shaped Nd-Fe-B magnets having *N* and *S* poles on the surface are put on the same axis and face each other. Rotating one of the ring magnets in the direction of its circumference, an oscillating force occurs on the other magnet. When this magnet is restricted to linear motion along the axis, the mechanical power driving the rotating magnet is transferred to the linear motion power. A pump was made with this mechanism. The efficiency of the pump is experimentally obtained, where water pressure difference between the intake and the outlet has been changed. As a result, the efficiency of the pump attains to about 45%. The efficiency of the actuator itself is very high, because the actuator has no copper and iron losses, and a negligibly small eddy current loss. © 1998 American Institute of Physics. [S0021-8979(98)19011-4]

I. INTRODUCTION

With the development of strong metal magnets, various types of magnetic actuators have been proposed.¹⁻³ Comparing electromagnetic solenoids and linear actuators with metal magnets, the actuators have some advantages. Metal magnets make positive and negative magnetic forces while the magnetic force in solenoids is only attractive. No hysteresis loss occurs in a metal magnet when the alternate magnetic field intensity around the magnet is less than a certain value. If a linear actuator has no winding for the exciting current, the linear actuator causes no copper loss which yields a large amount of heat in solenoids. If a linear actuator is driven at low frequency, the eddy current loss in a metal magnet is very small. We have proposed a linear actuator which satisfies all the conditions and has all the benefits mentioned above. And the actuator was applied to a pump.³

In this article, the efficiency of the pump is estimated with the output power of the actuator. Also, the output characteristics of the pump, which have been obtained by experiments, are shown.

II. FUNDAMENTAL MECHANISM

Figure 1 shows the fundamental mechanism of the proposed actuator. Two flat-ring-shaped magnets are facing each other with the distance *d*. Each magnet has two magnetic poles on both sides. For example, the opposite side of *N*-pole surface is *S* pole. By rotating the left magnet in the θ direction, push and pull forces occur on the right magnet. When the right magnet is restricted to linear motion, the magnet moves left and right alternately. As a result, the mechanical power driving the rotating magnet is transferred to the linear motion power. In order to make the magnetic field intensity yielding the forces large, the iron yoke is fixed to the rotating magnet on the left side. The push-pull force *f* occurring between the magnets in Fig. 1 is measured as a function of *d*

and θ (Fig. 2). The outer and inner diameters of the magnets are 27 and 15 mm, respectively. The thicknesses of the magnet and the iron yoke are 1.6 and 2 mm, respectively. The force pattern with respect to θ is like a triangular wave when the distance *d* is small.

A pump was made with the mechanism shown in Fig. 1. Figure 3 shows its structure. In order to have large output power of the pump, two pairs of rotating and linear motion magnets are used. The pump has two cylinders separated by a wall with two linear motion magnets. The force on each linear motion magnet is given by both of the rotating magnets.

III. OUTPUT CHARACTERISTICS

Figure 4 shows the experimental results of reciprocal linear motions of the wall in the pump, with respect to θ , when water pressure difference between the intake and the outlet has been changed from 0 mm H_g to 5.88 mm H_g. The origin of the wall position is the center between two rotating magnets in Fig. 3. The rotating speed is kept at 30 rpm in Fig. 4. The maximum displacement of the wall is restricted to ± 2.8 mm by stoppers.

In order to obtain the output power of the wall motion, *x-f* relation is calculated with the experimental results of Figs. 4 and 2, as shown in Fig. 5. Each area of the *x-f* loop corresponds to the output energy of one period of the wall motion for each pressure at 30 rpm. Figure 2 is used to transform θ in Fig. 4 to *f* in Fig. 5. The output power of the wall motion, *P*₁, is plotted in Fig. 6 with respect to the pressure *p*. The output power *P*₁ (mW) is obtained by dividing the output energy (mJ), the area of the *x-f* loop in Fig. 5, by 0.5 Hz (=30 rpm). The measured water flow from the pump, *Q*, is also plotted in Fig. 6. It is found from Fig. 6 that *P*₁ variation is between 20 and 25 mW at a constant speed of 30 rpm. On the other hand, water flow output is decreased with an increase of the pressure.

*P*₁ versus the rotating speed *n* is plotted in Fig. 7 for each pressure. Except for the case of *p* = 5.88 (mm H_g) over

FIG. 6. The output characteristics of the wall motion and the water flow characteristics of the pump, with respect to the pressure (30 rpm).

FIG. 7. The output characteristics of the wall motion with respect to the rotating speed.

FIG. 8. The output characteristics of the pump with respect to the rotating speed.

30 rpm, P_1 varies linearly with n ; also it is nearly the same for all the pressures studied. This result implies that each area of the x - f loop, corresponding to each P_1 , does not change considerably with respect to n and p .

Figure 8 shows the output characteristics of the pump with respect to n , obtained by the product of the measured pressure and the measured water flow. It is found from the figure that the pump output P_2 is approximately proportional to the rotating speed of the pump, n , except for the case of $p = 5.88$ (mm Hg) over 30 rpm.

From Figs. 7 and 8, we have the efficiency of the pump, as $\eta = P_2/P_1$, because the output power of the wall motion, P_1 , is regarded as the output power of the actuator. Figure 9 shows the efficiency characteristics of the pump with respect to the rotating speed n for each pressure. The efficiency η increases with an increase of the pressure and reaches about 45% when $p = 5.88$ (mm Hg).

IV. CONCLUSION

The efficiency of the proposed actuator itself is very high, because the actuator has no copper and iron losses, and

FIG. 9. The efficiency characteristics of the pump with respect to the rotating speed.

a negligibly small eddy current loss. We have experimentally obtained the output power of the actuator with the x - f loop given by the x - θ and f -(x, θ) relations. And we have evaluated the efficiency of the pump with the output power ratio between the pump and the actuator. As a result, approximately 45% efficiency is obtained. More than half of the output power of the actuator, $P_1 - P_2$, is supposed to be transformed to the fluid and mechanical losses of the pump.

A study of the temperature-dependent magnetic susceptibility and electrical resistivity $\rho(T)$ (0.5–300 K) on single-phase alloys (CaCu₅ type), prepared by argon arc melting, reveals a magnetic phase transition with a nonmonotonous decrease of the ordering temperature from $T_c = 115$ K for $x = 0$ to $T_c \approx 0$ for $x = 0.40$. A kink in the susceptibility at about 70 K indicates that ferromagnetism (at $x < 0.1$) transforms to a complex magnetic order for $0.125 \leq x \leq 0.35$. Above that concentration $\rho(T) = \rho_0 + AT^n$ changes from $n \approx 2$ to $n \approx 1.5$, a characteristic for non-Fermi-liquid behavior. Under pressure T_c stays almost constant for $x = 0.125$ but dT_c/dp grows with increasing Ru content. On the contrary, applied fields up to 12 T do not affect T_c . Low-temperature specific heat and ac susceptibility for $x = 0.40$ confirm the absence of long-range magnetic order down to 0.5 K. For $x = 0.35$ $C_p/T = 62$ mJ/mol K at 1.5 K, a value which is three times larger than that of CeRh_3B_2 .

I. INTRODUCTION

With respect to our general interest in the CaCu₅-type rare-earth intermetallics, the system $\text{Ce}(\text{Rh}_{1-x}\text{Ru}_x)_3\text{B}_2$ has attracted our attention because its low-temperature magnetic phase boundary is hitherto still uncertain. Former studies (e.g., Refs. 1–4) reported a rather drastic decay of ferromagnetic order from $T_c = 115$ K at $x = 0$ to $T_c = 40$ K at $x = 0.1$ followed by a paramagnetic phase. However, there is no detailed analysis of the critical region, where T_c is expected to approach zero. Knowing that magnetic instabilities usually are accompanied by non-Fermi-liquid (NFL) behavior, the present article is devoted to a thorough exploration of the above-mentioned phenomena.

II. EXPERIMENT

Alloys with the composition $x = 0.08, 0.125, 0.15, 0.2, 0.25, 0.3, 0.32, 0.35, 0.375$, and 0.4 were prepared by argon arc melting and were found to be single-phase CaCu₅ type from x-ray powder diffraction analysis. Physical properties like electrical resistivity under pressure (< 10 kbar) and fields (< 12 T), dc- and ac-magnetic susceptibility as well as specific heat, were investigated in the temperature region from 500 mK to 300 K; the low-temperature region below 10 K was studied using a ^3He cryostat.

III. RESULTS AND DISCUSSION

The volume change in $\text{Ce}(\text{Rh}_{1-x}\text{Ru}_x)_3\text{B}_2$ is found to be nonlinear and anisotropic with the a parameter increasing

FIG. 1. Unit cell dimensions for $\text{Ce}(\text{Rh}_{1-x}\text{Ru}_x)_3\text{B}_2$ as function of x .

FIG. 2. Unit cell dimensions for $\text{Ce}(\text{Rh}_{1-x}\text{Ru}_x)_3\text{B}_2$ as function of temperature for $x=0.2$ in comparison with data for CeRh_3B_2 (Ref. 4).

and c parameter decreasing with respect to pure CeRh_3B_2 (Fig. 1). Similarly, the temperature variation of c is much more pronounced than that of a . While a remains practically

FIG. 3. (a) Temperature dependence of the inverse susceptibility H/M at T for $x=0.125, 0.2$, and 0.4 . The arrows indicate the onset of magnetic order. (b) Magnetization vs field at 2 K .

FIG. 4. Temperature dependence of the electrical resistivity for $x=0.125, 0.15, 0.2, 0.3, 0.35$, and 0.4 . Solid lines are the fit to $\rho(T) = \rho_0 AT^2 \times \exp(-T/\Delta E)$. Inset: energy gap ΔE as a function of the Rh/Ru substitution.

constant, c increases significantly with increasing temperature. This observation refers to CeRh_3B_2 (Ref. 4) as well as to $\text{Ce}(\text{Rh}_{0.65}\text{Ru}_{0.35})_3\text{B}_2$ (Fig. 2).

A study of the temperature-dependent magnetic susceptibility M/H and electrical resistivity (Figs. 3 and 4) reveals a magnetic phase transition with a nonlinear decrease of the ordering temperature from $T_c = 115\text{ K}$ for $x=0$ to $T_c \approx 0$ for $x=0.40$. While in literature¹ $T_c \approx 0$ is extrapolated to $x \approx 0.13$, we still observe an anomaly in magnetic susceptibility and resistivity within the concentration range for $0.125 \leq x \leq 0.35$. This suggests the presence of magnetic correlations which peak at $T_m^{\text{max}} = 67\text{ K}$ and $x=0.2$. Above this temperature, the susceptibilities, recorded for the alloys with $x=0.125, 0.2$ can be analyzed in terms of a modified Curie-

FIG. 5. Pressure dependence of magnetic ordering temperature up to 10 kbar for $x=0.125, 0.2$, and 0.3 .

FIG. 6. Tentative magnetic phase diagram for the system $\text{Ce}(\text{Rh}_{1-x}\text{Ru}_x)_3\text{B}_2$. The magnetic state of the shaded region is not determined yet.

Weiss law yielding effective magnetic moments $\mu_{\text{eff}} = 1.5\mu_B$ ($\Theta_p = -16$ K) and $1.3\mu_B$ ($\Theta_p = -56$ K), respectively. The temperature-dependent susceptibility may alternatively be accounted for by crystal field contributions and indeed is well fitted [solid line in Fig. 3(a)] assuming a pure $|\pm 1/2\rangle$ doublet ground state and a first excited $|\pm 5/2\rangle$ level at 850 and 1090 K, respectively (Fig. 3). The $|\pm 3/2\rangle$ state as uppermost level is at substantially higher energies. For such a level scheme, no contribution from hybridization was adopted. Figure 3(b) displays isothermal magnetization measurements at $T = 2$ K for $x = 0.125, 0.2$, and 0.4 . As the Ru content increases, the magnetization diminishes, however, the observed overall values are extremely small.

Within the ordered region, the concentration dependent variation of the magnetic contribution to the electrical resistivity corresponds to a crossover from long-range ferromagnetism (low Ru content) to a complex magnetic order. The latter conclusion is drawn from the low-temperature behavior of the resistivity according to $\rho(T) = \rho_0 + AT^n \times \exp(-T/\Delta E)$, where $n = 2$ and ΔE accounts for a gap in the spin wave spectrum. A least-squares fit to the data indicates that the energy gap correlates with the magnetic ordering temperature, again with a maximum value of $\Delta E/k_B \approx 225$ K at $x = 0.2$. Furthermore, $\rho(T)$ is almost independent on fields up to 12 T.

The pressure dependence of the ordering temperature of $\text{Ce}(\text{Rh}_{1-x}\text{Ru}_x)_3\text{B}_2$ has been evaluated from resistivity measurements (Fig. 5). While T_c stays almost constant for $x = 0.125$, increasing Ru content invokes a higher influence

of pressure upon T_c . On the contrary, applied fields do not affect T_c .

As the magnetic order vanishes due to Rh/Ru substitution ($x > 0.35$), the temperature dependence of the electrical resistivity changes to a power law with an exponent close to 1.5 (for $T < 30$ K). Such a dependence is inconsistent with Fermi liquid behavior.

A low-temperature study of the specific heat for $x = 0.40$ confirmed the absence of long-range magnetic order and revealed a C_p/T value for $T = 1.5$ K of about 66 mJ/mol K^2 , which is about three times larger than that of CeRh_3B_2 .

A tentative fit of the specific heat data of $\text{Ce}(\text{Rh}_{0.6}\text{Ru}_{0.4})_3\text{B}_2$ below about 1.5 K according to $C_p/T = a \ln(T/T_0)$ yields a logarithmic divergence ($a < 0$) and a characteristic temperature $T_0 \approx 300$ K. In agreement with the resistivity results and according to a universal scaling² of the form $(C_p/T - E)T_0 = -7.2 \log(T/T_0)$, where E accounts for the conduction electron system, a NFL state of this alloy is confirmed. In the scope of Doniach's model for Kondo lattices the Rh/Ru substitution is responsible for a shift of the system from a region with low values of $J \cdot N(E_F)$ to large values of this parameter (here J is the s - f coupling constant and $N(E_F)$ is the electronic density of states at the Fermi energy). Hence, magnetic order vanishes and the dependence of T_c on pressure becomes significant. A tentative version of the magnetic phase diagram for the region $0 < x < 0.4$ is shown in Fig. 6.

In summary, the presented results on the physical behaviour in the alloy system $\text{Ce}(\text{Rh}_{1-x}\text{Ru}_x)_3\text{B}_2$ define the appearance of an additional magnetic state with rather small ordered moments in the concentration range $0.12 < x < 0.35$. Above this composition a non-Fermi-liquid behavior is observed.

Neutron diffraction and specific heat measurements have been performed to study the magnetic ordering of the Ce ions in the heavy-fermion compound Ce_3Al . Detailed crystal structure analysis, determined using high resolution neutron diffraction patterns and Rietveld method, shows that the Ce ions may be grouped into two types: one in the Ce–Al chain, the other in the Ce–Ce chain. The specific-heat data reveal an anomaly at $T \approx 2.2$ K, but the calculated magnetic entropy is much smaller than the expected $R \ln 2$ if all Ce spins ordered. Low temperature neutron diffraction measurements confirm that the transition at 2.2 K is magnetic and is associated with the ordering of the Ce spins. The magnetic unit cell is double the nuclear one along the a and c axes, and contains 48 Ce ions. Only the Ce ions in the Ce–Al chains participate in the ordering at 2.2 K, and they are coupled antiferromagnetically. © 1998 American Institute of Physics. [S0021-8979(98)21011-5]

The unusual properties found in heavy-fermion systems continue to generate renewed interest in the f -electron materials. Their physical origin is believed to effectively arise from the strong coupling between the conduction electrons and the fluctuating f -electron moments.^{1,2} Among the Ce-based compounds, the family Ce_xAl_y has attracted considerable attention. On the magnetic side, antiferromagnetic order has been observed in CeAl and CeAl_2 , whereas no ordering was found down to 0.6 K in CeAl_3 . Previous studies^{3,4} have shown that the thermodynamic, magnetic, and transport properties of intermetallic Ce_3Al behaves as a heavy-fermion system. Above 520 K, Ce_3Al crystallizes into the cubic Cu_3Au type of structure (β - Ce_3Al), below which it transforms into the hexagonal Ni_3Sn type of structure (α - Ce_3Al). Another structural transition occurs at 115 K, below which monoclinic (but very close to orthorhombic) symmetry was found (γ - Ce_3Al).⁵ A Kondo effect develops below 20 K, and antiferromagnetic ordering is expected at ~ 2.5 K. In this article, we report studies made on the ordering of the Ce spins in γ - Ce_3Al , by using specific heat and neutron diffraction measured at low temperatures. A relatively small value for the magnetic entropy was observed, and only a portion of the Ce spins orders in a simple antiferromagnetic arrangement at $T_N \approx 2.2$ K.

A polycrystalline sample of Ce_3Al was prepared by arc melting high-purity cerium (99.99%) and aluminum (99.9999%) in a helium atmosphere. The arc-melting process was repeated 20 times to obtain a more homogeneous sample. After arc melting, the ingot was sealed in vacuum, followed by annealing at 500 °C for 3 days and then 200 °C for another three weeks to relieve strains and promote conversion from the cubic to hexagonal phase. Ce_3Al is highly ductile, and is quite stable against oxidation. The fabricated

sample was characterized using high resolution neutron diffraction and Rietveld analysis,⁶ covering a range in temperature from 300 to 12 K. At 300 K, α - Ce_3Al was found with essentially no unexpected peaks present. We estimated the impurity levels to be less than 1%. Below 110 K, both α - Ce_3Al and γ - Ce_3Al were present, with the γ phase gradually becoming dominate with reducing temperature. At 12 K, it shows 92% γ - Ce_3Al phase and 8% α - Ce_3Al phase, with monoclinic lattice parameters $a = 6.8212(6)$ Å, $b = 12.458(1)$ Å, $c = 5.3587(4)$ Å, and the angle between the a and b axes $\gamma = 89.96(1)^\circ$.

The specific heat data were taken on a 9 mg thin specimen employing the time constant technique.⁷ Shown in Fig. 1 is the temperature dependence of the specific heat below 25 K. The main feature seen is the peak at $T = 2.2$ K, which is associated with the ordering of the Ce spins (see below).

FIG. 1. Temperature dependence of the specific heat. The peak at 2.2 K is associated with the ordering of the Ce spins. The solid curve shows the contributions from phonons and conduction electrons. Shown in the inset is the magnetic entropy calculated from the magnetic specific heat data.

^{a)}Electronic mail: whli@joule.phy.ncu.edu.tw

FIG. 2. Magnetic diffraction pattern obtained at $T=0.4$ K, where the indices shown are based on the nuclear unit cell. The solid curves are fits of the peaks to the Gaussian instrumental resolution function.

Above 10 K, the contribution from phonons becomes dominant. The solid curve shown is a fit of the data obtained between $15 \text{ K} \leq T \leq 40 \text{ K}$ (not shown) to the expression $C(T) = \gamma T + \beta T^3$, with $\gamma = 95 \text{ mJ/mol-Ce-K}^2$ for the contribution from electrons and $\beta = 0.77 \text{ mJ/mol-Ce-K}^4$ from phonons. The value obtained for the linear coefficient γ is about two orders of magnitude larger than that for ordinary metals. It is, however, still smaller than what is usually obtained for heavy-fermion compounds.

The magnetic contribution to the specific heat C_m may be isolated by subtracting the phonon and electron terms discussed above from the observed data. Shown as an inset in Fig. 1 is the magnetic contribution to the entropy, determined by calculating the area beneath the C_m/T versus T curve. We may expect that the low crystal symmetry of monoclinic $\gamma\text{-Ce}_3\text{Al}$ should split the $J=5/2$ line for Ce into three doublets. An integrated entropy of $R \ln 2 = 5.76 \text{ J/mol K}$ is then anticipated for the ground state. The observed value, however, is substantially smaller at all temperatures shown. This may indicate only a fraction of the entropy of a doublets is liberated at the magnetic phase transition.

Neutron diffraction experiments were conducted at the US NIST Research Reactor. Data were collected on the BT-9 triple-axis spectrometer operated in double-axis mode without using an analyzer crystal. The incoming neutrons had a wavelength of 2.352 \AA defined by a pyrolytic graphite (PG) (002) monochromator, with a PG filter placed in front of the monochromator to suppress higher-order wavelength contaminations. Collimators with horizontal divergences of $40'$, $48'$, and $48'$ full width at half maximum acceptance were used for the in-pile, monochromatic, and diffracted beams, respectively. The samples were mounted in an aluminum can filled with helium exchange gas to facilitate thermal conduction at low temperatures. A pumped ^3He cryostat was used to cool the sample, and the lowest temperature achieved was 0.4 K .

Figure 2 shows the magnetic diffraction peaks that develop as the temperature is reduced from 4 to 0.4 K . These data are obtained by subtracting the diffraction pattern taken at 4 K from the one taken at 0.4 K . This magnetic diffraction pattern originates from the Ce spin ordering. The solid

FIG. 3. The proposed spin configuration. Only the Ce in the Ce-Al chains order, with $T_N \approx 2.2 \text{ K}$.

curves shown are fits of the data to the Gaussian instrumental resolution function, and the peaks may all be indexed (as shown) based on the monoclinic nuclear unit cell. A half-integer value for the Miller's index means that the length of the magnetic unit cell along the corresponding axis is double that of the nuclear one. The magnetic unit cell is then double the nuclear one along both the a and b axis directions. It contains 48 Ce ions, since there are 12 in each nuclear unit cell.

The arrangement of the Ce spins can be determined from the relative intensities of the magnetic peaks.⁸ Although the structure of the γ phase is complicated, it, however, can be viewed as consisting of slightly tilted Ce-Al and Ce-Ce chains (hence Ce_3Al) along the a axis alternately stacked along both the b and c axis directions, as shown in Fig. 3. Finding the spin arrangement is not a simple matter in the present case, since there are 48 Ce ions in the magnetic unit cell. We tried over 80 models, each with a different spin arrangement, considering essentially all possible arrangements including collinear and noncollinear structures. Starting with the assumption that all Ce spins are ordered, we found two models that could describe the correct d spacings for the observed magnetic pattern. However, the spin direction was found to be arbitrary, leading us to believe that the models were not physical. We next tried models assuming either only the Ce in the Ce-Ce chains or those in the Ce-Al chains order. No satisfactory models were found in the former case, while the model in which the Ce spins in the Ce-Al chains are aligned antiparallel with no moments on the Ce in the Ce-Ce chains, was found to describe the observed pattern fairly well. The spin structure of this proposed model is shown in Fig. 3, and comparisons between the observed and calculated intensities are listed in Table I. We note that the goodness of the fit of this proposed model is the best among all models studied. This result of only a portion of the Ce spins participates in the magnetic order at this

TABLE I. Observed and calculated magnetic integrated intensities at 0.4 K. The intensities are normalized with respect to the $\{1/2\ 2\ 1/2\}$ intensity.

Miller index (<i>h k l</i>)	Scattering angle (deg.)		Integrated intensity	
	Observed	Calculated	Observed	Calculated
(1/2 0 1/2)	16.1	15.9	1.18	1.29
(1/2 1 1/2)	19.1	19.3	2.81	2.98
(1/2 2 1/2)	27.1	27.1	1	1
(3/2 1 1/2)	34.1	34.4	0.30	0.27
(1/2 3 1/2)	36.8	36.8	0.96	0.90
(3/2 2 1/2)+(1/2 0 3/2)	39.2	39.5	1.04	0.76
(1/2 2 3/2)	45.4	45.7	1.05	1.19
(3/2 3 1/2)	47.0	46.9	0.19	0.26
(1/2 4 1/2)+(1/2 1 3/2)	47.5	47.5	0.23	0.58

transition is consistent with the conclusion made in a separate study⁴ based on specific heat and resistivity measurements. Dividing the rare-earth ions into two sublattices has been suggested for the Ce in CeAl as well, where different magnetizations (magnitude and direction) were proposed for the two sublattices.⁹

The variations of the $\{\frac{1}{2}0\frac{1}{2}\}$ and $\{\frac{1}{2}1\frac{1}{2}\}$ peak intensities with temperature are shown in Figs. 4(a) and 4(b), respectively. Both plots reveal basically the same temperature dependence, and a typical order-parameter curve for polycrystalline samples. On cooling, the intensity starts to grow around 2.5 K, increasing in the usual way, and reaching saturation around 1 K. The ordering temperature for the Ce spins, as determined by the inflection point of the $\{\frac{1}{2}1\frac{1}{2}\}$ curve, is $T_N \approx 2.2$ K. This ordering temperature matches the temperature at which the peak in $C(T)$ occurs. By comparing the $\{\frac{1}{2}2\frac{1}{2}\}$ integrated intensity to the $\{110\}$ nuclear one, we obtained the low temperature saturated moment of $\langle \mu_z \rangle = 1.24(3) \mu_B$ for each Ce ions.

In summary, we have performed specific heat and neutron diffraction measurements to study the ordering of the Ce spins in a polycrystalline Ce₃Al. Intermetallic Ce₃Al may be classified as a heavy-fermion system, as its electronic specific heat is much larger than that of ordinary metals. However, the electrons in Ce₃Al are not as heavy as those in other heavy-fermion systems like CeAl₃ and UPt₁₃. Below 110 K, Ce₃Al transforms gradually from hexagonal α phase into monoclinic γ phase with reducing temperature. A magnetic

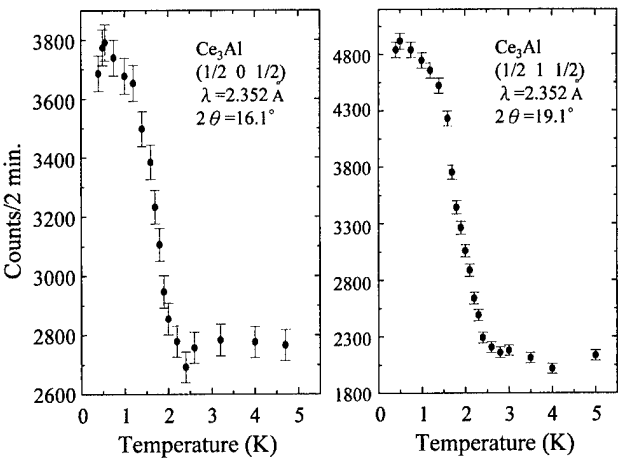

FIG. 4. Temperature dependence of the $\{\frac{1}{2}0\frac{1}{2}\}$ and $\{\frac{1}{2}1\frac{1}{2}\}$ peak intensities, showing the variation of the square of the staggered magnetization with temperature.

transition associated with the ordering of the Ce spins was observed to occur at $T_N \approx 2.2$ K. Only those Ce ions located on the Ce–Al chains participate in this ordering. The coupling is antiferromagnetic in nature, and a simple collinear antiferromagnetic spin arrangement was found. However, the calculated entropy is about 40% smaller than the observed value. We believe that crystalline electric field effect plays an important role in this issue, and inelastic neutron scattering measurements are needed to resolve this point.

Size and dimensionality effect in single-impurity Anderson model

Feng Chen and Nicholas Kioussis^{a)}

Department of Physics, California State University Northridge, Northridge, California 91330-8268

The dimensionality and the size effect on the magnetic properties of the single-impurity symmetric Anderson model in three-, two-, and one-dimensional lattices has been studied using the quantum Monte Carlo method. We have considered clusters with odd number of sites with the impurity placed at the center of the cluster and have employed open boundary conditions. In 3D and 1D lattices, we find that at sufficiently low temperatures, the system can be in either a spin compensated or noncompensated state as the cluster size is reduced. On the other hand, in 2D the system is always in a spin-compensated state independent of the cluster size. These results imply physics beyond that contained in the simplest Kondo model and may explain the discrepancy between two recent experimental results. © 1998 American Institute of Physics. [S0021-8979(98)30811-7]

The Kondo effect involves the interaction of a localized moment with an electron gas and is relevant to the behavior of dilute magnetic alloys, as well as concentrated systems such as the heavy-fermion materials. The ground state of the single-impurity Kondo problem is a singlet in which the local moment is "compensated" by the conduction electrons due to the antiferromagnetic exchange interaction between the local moment and the conduction electrons.¹ Several calculations predict that the length scale of the compensation cloud is of the order $R_K \approx \hbar v_F / 2\pi k_B T_K$.² On the other hand, several experiments suggest that the length scale is of an order of magnitude smaller than the theoretical value or that the polarization cloud may not even exist.³ Thus surprisingly, despite the large amount of work on the Kondo problem, it appears that the question of length scale is far from settled.

Nearly all of the work on the single-impurity Kondo problem has involved bulk, i.e., three-dimensional systems. However, in recent years the behavior and the properties of the spin-compensation cloud in lower-dimensional (quasi-one and quasi-two dimensional) systems have attracted much attention both experimentally⁴⁻⁸ and theoretically.^{9,10} Since a length scale (R_K) is associated with the Kondo effect, one might expect the Kondo behavior to be different in a small system (as compared to a "bulk" sample), provided that one or two dimensions are small compared to the relevant length scale R_K . The experimental results can be summarized as follows: (i) A large size dependence was found for Au(Fe) and Cu(Fe) thin films (for film thickness less than 2000 Å), where the Kondo contribution to the resistivity is suppressed;⁴ (ii) no size dependence of the Kondo resistivity was found in Au(Fe) wires when the width dependence of the electron-electron interaction contribution to the resistivity was taken into account;⁷ and (iii) the Kondo temperature T_K shows no size dependence.⁶

The purpose of this paper is to investigate the effect of: (1) the size of the system and (2) the dimensionality on the ground-state properties of the single-impurity Anderson model. Although the effect of size on the Friedel resonance

was studied recently by Bergmann,¹² to our knowledge, the effect of dimensionality on the ground-state properties has not been studied theoretically. In reduced dimensions, systems may exhibit anomalous properties. For example, the Van Hove singularities in the density of states and the nested Fermi surface in a two-dimensional lattice or the charge-density instability in one dimension may effect the ground state properties of the Kondo problem.

Quantum Monte Carlo methods have been used previously to study the single-impurity Anderson model and have provided great insight into the magnetic properties.^{13,14} However, while in all previous simulations the magnetic impurity is placed in a three-dimensional infinite sea of conduction electrons, in the present work the conduction electrons are confined on a regular lattice. In order to study the size effect, we employ open boundary conditions and place the magnetic impurity in the middle of the lattice. In open boundary conditions, conduction electrons that reach the boundary sites can hop only back to interior sites. We have changed the dimensionality and the size of the lattice and have studied the local moment and the temperature dependent impurity susceptibility. The results of the numerical simulations indicate that the properties of the ground state are quite different than those for the bulk systems depending on the dimensionality and the size of the lattice, and may explain the discrepancy between two recent experimental results.⁵⁻⁷

The single-impurity Anderson model is

$$H = -t \sum_{\langle i,j \rangle \sigma} (c_{i\sigma}^+ c_{j\sigma} + H.c.) + E_d \sum_{\sigma} d_{\sigma}^+ d_{\sigma} + U n_{d\uparrow} n_{d\downarrow} + V (c_{i_0\sigma}^+ d_{\sigma} + h.c.), \quad (1)$$

where $c_{i,\sigma}^+$ creates a conduction electron on site i with spin σ , d_{σ}^+ creates a localized electron on the impurity site i_0 with spin σ , E_d is the energy of a singly occupied impurity level, U is the Coulomb interaction between two d electrons on the impurity site, and V is the on-site hybridization energy between the conduction-electron orbital and the impurity-electron orbital.

We have used a finite-temperature Monte Carlo technique with an exact updating procedure. A typical Monte

^{a)}Electronic mail: nkoussi@newton.csun.edu

Carlo run involved 5000 sweeps through the lattice and the statistical error for the quantity measured was negligible except where shown. The finite time slice $\delta\tau$ introduces a systematic error. Simulations with $\delta\tau=0.125$ and 0.25 give results which differ only by a few percent. As a check on our Monte Carlo algorithm we have done extensive comparison with exact diagonalization results for an impurity interacting with a two-site conduction-electron lattice. We consider the symmetric case with $E_d = -U/2$, which is the most favorable for the formation of an impurity magnetic moment, and the case of half-filled conduction band and one localized d electron. This choice ensures particle-hole symmetry. The Monte Carlo simulations were carried out in the intermediate parameter regime, where the correlation effects are comparable in size to the hybridization interaction, i.e., $U/t = V/t = 1$. In the intermediate regime Monte Carlo simulations provide essentially exact results, whereas analytic approaches are most likely to fail or be inaccurate.

In order to investigate the effect of size and dimension on the spin-compensation cloud, we have calculated the impurity local moment:

$$\langle(\sigma_z^d)^2\rangle = \langle(n_{d\uparrow} - n_{d\downarrow})^2\rangle. \quad (2)$$

FIG. 1. Local magnetic moment, $\langle(\sigma_z^d)^2\rangle$, vs cluster size L^n for $U=1$, $V=1$, and $\beta=16$ in (a) a 3D cubic lattice, (b) a 2D square lattice, and (c) a 1D lattice.

In Fig. 1 we show the local moment, $\langle(\sigma_z^d)^2\rangle$, versus the cluster size (L^n for n dimension) for three [Fig. 1(a)] two, [Fig. 1(b)] and one dimension [Fig. 1(c)] at low temperatures $\beta=16/t$. One can see that the local moment in one and three dimensions oscillates as the lattice size is reduced. This result indicates that for 3D and 1D there are two different types of ground states, a compensated one (for $L=5$, nine sites) and an uncompensated one (for $L=3$, seven sites). The local magnetic moment associated with the uncompensated ground state is larger than that of the compensated state and shows a larger size effect. The moment decreases exponentially with lattice size, $\mu \propto e^{-L/L_0}$, where L_0 is 7.6 for 3D and 12.8 for the 1D lattice. On the other hand, the local moment in 2D varies monotonically with lattice size, indicating the existence of one type of ground state only, the compensated one.

The size effect in 1D can be understood by examining the Anderson-Hamiltonian for $U=0$ which can be diagonalized exactly. The eigenfunctions in 1D can either be of odd or even parity depending on the number of sites in the system. The eigenfunctions of even (odd) parity have a large (small) spectral weight on the impurity site which gives rise

FIG. 2. Impurity magnetic susceptibility vs $\log_2 T$ for $U=1$ and $V=1$ for (a) 3D lattice, (b) 2D lattice, and (c) 1D lattice, for the cluster size $L^n = 3^n$ and $L^n = 5^n$, respectively.

to a strong (weak) antiferromagnetic interaction between the local and conduction electrons. Thus, for cluster size of $L = 3, 7, \dots$ the states at the Fermi energy are of odd parity giving rise to an "uncompensated" state, whereas for $L = 5, 9, \dots$ the states at the Fermi energy are of even parity giving rise to a "compensated" ground state.

In order to gain further insight of the nature of the ground state, we have calculated the impurity d -spin magnetic susceptibility

$$T_\chi = \int_0^\beta d\tau \langle \sigma_z^d(\tau) \sigma_z^d(0) \rangle, \quad (3)$$

as a function of temperature. In Fig. 2, we plot the "effective moment," T_χ , vs $\log_2 T$ for three [Fig. 2(a)], two [Fig. 2(b)], and one dimension [Fig. 2(c)] for the cluster size $L^n = 3^n$ and $L^n = 5^n$ (n is the dimension), respectively. If the ground state is compensated, the effective moment, T_χ , should decrease to zero at lower temperatures, signaling the quenching of the local moment. In Fig. 2, we plot these calculations with $L = 3$ and 5. It is clear that in 3D and 1D, the ground state can be either a compensated ($L = 5$) state or an uncompensated ($L = 3$) state, while the ground state in the 2D lattice can only be a compensated state.

In order to check the effect of boundary conditions on the ground state properties, we have also carried out Monte Carlo simulations for systems with even number of sites employing periodic and antiperiodic boundary conditions. The results for the size and dimensionality effect on the ground state properties are similar to those reported in this work for the case of systems with odd number of sites with open boundary conditions.

The absence of a size effect in our calculations for the 2D lattice is consistent with the experimental results of Chandrasekhar *et al.*⁷ On the other hand, the presence of a size effect in 3D is consistent with the experimental results of Giordano *et al.*^{5,6} The Kondo temperature inferred from the temperature dependence of the impurity magnetic susceptibility does not depend on the system size in 1D, 2D, and

3D lattices, which is consistent with the experimental results.⁵⁻⁸ It is interesting to consider the case of a magnetic impurity doped quantum dot, although no experimental results are currently available. Our results in 1D suggest that the ground state of the quantum dot can be a compensated or an uncompensated state as the size of the wire is reduced.

In conclusion, the dimensionality of the conduction electrons affect their interaction with the impurity resulting in a compensated or an uncompensated ground state for the case of 3D and 1D depending on the lattice size, and to a compensated ground state for the case of 2D. The dimensionality and size effect are consistent with the experimental results for the Kondo resistivity anomalies in doped films and wires. We predict that there should be a large size effect in doped quantum dots.

***f*-Electron delocalization/localization and the abrupt disappearance of uranium magnetic ordering with dilution alloying**

B. R. Cooper^{a)} and Y.-L. Lin

Department of Physics, West Virginia University, Morgantown, West Virginia 26506-6315

We have applied the model and technique previously applied to the change of Curie temperature with pressure for correlated-electron uranium systems to predict the change in Curie temperature and ordered moment with dilution alloying. The theory is remarkably successful in its predictions, and this success has important implications for the overall understanding of magnetic ordering in correlated-electron systems including heavy fermion systems. For US, the dilution alloying behavior found experimentally is dramatic. In $U_xLa_{1-x}S$, the magnetic ordering abruptly disappears at about 55% uranium. Our *ab initio*-based theory quantitatively predicts this abrupt disappearance while also quantitatively predicting the monotonic decrease of Curie temperature with pressure for undiluted US. In addition, in agreement with experiment, the theory predicts the correct trend for the magnetic ordering to disappear with dilution, while at the same time absolutely and quantitatively predicting the nonmonotonic variation of Curie temperature with pressure, for USe and UTe. The *ab initio*-based model gives absolute material-specific predictions using input from the local density approximation paramagnetic uranium *f*-electron-projected density of states plus *ab initio* calculated values of the correlation energy U . The key physics of the model is the recognition and quantification of the concept that the *f* spectral density in the vicinity of a specific uranium nucleus (so-to-speak in the muffin-tin sphere) can either be in a stable f^3 configuration for a long enough period of time that, through coupling to other such stable f^3 sites, it can magnetically order, or can be in a situation such that the configuration fluctuates rapidly between f^3 and f^2 , and for purposes of magnetic ordering acts like a hole in the *f*-electron lattice in the same way that substitution of lanthanum for uranium creates a hole. Both pressure and dilution alloying, by causing an increase in *f*-delocalization, increase the fraction of uranium sites in the rapidly fluctuating, magnetically ineffective, condition. For dilution alloying, at a certain point this increase in fluctuations causes the stable f^3 component to fall abruptly below a critical value necessary to sustain any magnetic ordering, and hence brings about a catastrophic collapse in magnetic ordering. © 1998 American Institute of Physics. [S0021-8979(98)21111-X]

I. INTRODUCTION AND PHYSICAL PICTURE

The magnetic ordering of the NaCl-structure uranium monochalcogenides under high pressure and upon dilution alloying experimentally provides extremely interesting physics. This includes the nonmonotonic variation of the Curie temperature (T_c) under pressure¹⁻³ for USe and UTe and the abrupt disappearance of magnetic ordering in $U_xLa_{1-x}S$ at about 55% uranium (far above the percolation limit)^{4,5} and similar behavior for⁶ diluted USe and UTe. By dilution alloying, we mean alloying as in the case of $U_xLa_{1-x}S$, where one can alter the magnetic interactions among the *f*-electron ions by an alloying process that keeps the background non-*f* chemical environment essentially unchanged. Except for a small change in lattice constant, magnetically this simply creates "holes" at those lattice sites where, e.g., lanthanum replaces uranium in US. Understanding this physics, as described below, provides us with valuable insight into the mechanisms controlling magnetic ordering in systems of partially delocalized *f* electrons (cerium and light actinides) that hybridize with non-*f* band electrons in the presence of on-site coulomb repulsion. This understanding and the method-

ology developed, in fact, gives us a quantitative material-predictive theory for the magnetic ordering aspects of heavy fermion behavior.

The central problem of treating magnetism in cerium and light actinide compounds with metals and metalloids is how to deal with the *f* delocalization in energy and space and the associated hybridization of the *f* electrons with *p* or *d* electrons coming from other atoms. To improve this treatment, in effect, means improving the treatment of correlation effects.

In past work,⁷⁻⁹ we have discussed how the physics can be captured by including two-electron correlations involving a single on-site *f* electron and a single *l* (*p/d*) electron of off-site parentage as well as on-site *f*-*f* correlations. In model calculations,⁷ we have shown that this leads to the possibility of narrow singlet (nonmagnetic) and triplet (magnetic) bands "competing" to be the ground state of the system. This then reproduces the range of specific heat and susceptibility behavior characteristic of heavy fermion systems, where it is essential to include the temperature dependence of the Fermi energy in the calculations. In effect, the essential feature of the Kondo effect, the possible formation of a spin-singlet state as the ground state and the competition with a magnetic state to provide the ground state, is already present at the level of including only two-electron correla-

^{a)}Electronic mail: bcooper@wvu.edu

tions. Thus the use of the impurity Kondo model and the resulting Kondo resonance (see Ref. 10 for a discussion) is not required to explain heavy fermion phenomenology. We have also shown^{8,9} that essentially the same singlet/magnetic state picture arises when we include two-electron $f-l$ and $f-f$ correlations for actinides, which have atomic f^n configurations with $n > 1$. We have outlined⁹ a practical electronic structure scheme for real materials based on a sequence in which a conventional one-electron electronic structure calculation is followed by a calculation for the lattice with a heliumlike two-electron hamiltonian at the f -atom sites. This procedure will reconstruct the LDA bands to include two-electron texturing, i.e., will impose a substructure of extremely narrow nonmagnetic and magnetic bands leading to the phenomena modeled in Ref. 7 depending on where the Fermi energy falls with respect to this extreme narrow-band substructure.

In order to treat specific observable spectral features and their thermodynamic (e.g., specific heat, susceptibility) and transport property consequences, we would have to carry out the two-electron computational procedure outlined in Ref. 9. At present, we have not yet carried out calculations using the procedure outlined in Ref. 9. However, because they are global properties (i.e., involve the spectral density in an integrated sense), we can nevertheless perform *ab initio*-based calculations for the Curie temperature and ordered moment. Such calculations were first described in Ref. 11 for the Curie temperature variation with pressure and here are refined and extended to treat the Curie temperature and ordered moment change with dilution alloying as well as the change of T_c with pressure.

The *ab initio*-based model of Ref. 11, as refined and extended here, gives absolute material-specific predictions using input from the uranium f -electron-projected paramagnetic LDA density of states from supercell calculations plus the *ab initio*-calculated correlation energy U . There is one arbitrary feature: how to separate the localized f spectral density from the delocalized f spectral density. We adopt a boundary defined by the energy where, upon decreasing energy from the $j = 5/2$ peak in the density of states, there is a distinct difference between the total and the f -projected density of states. (In effect, this is the energy where significant hybridization begins to occur between the f electrons and the non- f band electrons. Operationally, we define this as the energy where the density of states first stops dropping monotonically from the peak, i.e., the first local minimum in the density of states.) Once this is done, there is only one non-*ab initio* number that must be provided for a given material, e.g., US. This is setting the starting (baseline) division between occupation of uranium states where an f^3 (magnetic) configuration exists for long enough for those sites to be able to magnetically order and those states which fluctuate between an f^2 configuration and an f^3 configuration sufficiently rapidly to, in effect, provide magnetic holes in much the same way as a La site. We choose that single number (i.e., the baseline fraction of uranium sites with stable f^3 configuration) for the pure (unalloyed) material (e.g., US) at ambient pressure.

The catastrophic ordered magnetic moment collapse that occurs at 55% uranium for $U_x\text{La}_{1-x}\text{S}$ is then a consequence of three effects providing an extremely nonlinear magnetic response to the dilution: most importantly, the increased delocalization acts wholly to reduce the stable f^3 component, secondarily that f^3 component becomes more localized, hence giving less coupling for a given f^3-f^3 separation, and in addition the f^3 sites are spread further apart with increasing lanthanum dilution. While probably secondary in triggering the ordered moment collapse, the extreme localization, as it disappears, of the remaining f^3 component, may be central to the observation of heavy fermion effects.

II. CALCULATIONAL PROCEDURE

Using the Hubbard model, following the procedure described in Ref. 11, the coupling (J) between localized moments on an fcc lattice is obtained from the width of the localized peak in the uranium f -electron-projected density of states and the calculated correlation energy (U). If t is the interatomic interaction, then for an fcc lattice, the localized peak width Γ is related to t through $\Gamma = 1.04t$ and $J = t^2/U$. The magnetic ordering is then calculated exactly as in Ref. 11 for an Ising lattice (used to mimic the very large magnetic anisotropy) with holes.

The key point is to identify the number of holes, i.e., the average number of sites not occupied by stable f^3 uranium. We do this by first establishing a baseline fraction of stable f^3 sites for the pure unalloyed material at atmospheric pressure. This is the one point at which we either insert a physically motivated guess or use one piece of experimental data or use a value to balance between fitting several pieces of data. The obvious choices for this purpose are the low-temperature ordered moment, the Curie temperature, or the LDA f -electron count. For US all three of these indicate very closely the same baseline value. The experimental low-temperature ordered moment per uranium of US from the recent neutron measurements of Ref. 5 is $1.60 \mu_B$, and from the magnetization measurements of Ref. 4 is $1.55 \mu_B$. This is slightly less than half the ordered moment expected for U^{3+} (f^3 uranium) ($3.27 \mu_B$). This would give a baseline fraction of stable f^3 of 0.49. The LDA f count is close to 2.5 for US, indicating a baseline f^3 fraction of 0.5. In addition, for US as discussed below with that choice of 0.5, the calculated T_c is 183 K compared to the experimental value of^{4,5} 180 K. So we take the baseline value of holes as 50% for pure US at atmospheric pressure. (This is a different baseline than in Ref. 11, and there are also some changes in the technical details. Thus the predicted variation of Curie temperature with pressure shown below differs somewhat from that of Ref. 11.)

For US and UTe, our choice of the starting baseline fraction of stable f^3 uranium guided by the data of Ref. 12 and the LDA f counts is 0.67 and 0.80, respectively. It is this greater degree of localization, of having more stable f^3 , on going from US to USe to UTe that gives rise to the dramatically different variation of T_c with pressure.

Then the key input information from the LDA calculations is how this baseline number of holes increases with pressure and dilution alloying as the hybridization with the

FIG. 1. Calculated Curie temperature for US compared to experiment for change with La dilution in (a) (experimental results from Ref. 5) and for change with pressure in (b) (experimental results from Ref. 3).

p/d electrons increases. We do this by calculating the decrease in integrated f -spectral weight per uranium contained in the localized peak of the LDA density of states. Thus for US, for pressure effects, the increase in holes comes wholly from the size of that spectral transfer, which decreases the 0.5 electron per uranium that on average defines the baseline fraction of well ordered f^3 uranium.

For dilution alloying, there are two ways in which the number of holes increases, by the shift of spectral weight per uranium from the localized peak to the itinerant tail (an illustrative figure and illustrative numerical results for the previous pressure calculation can be seen in Ref. 11), i.e., the same effect as caused by pressure. In addition, substitution of a lanthanum by itself gives a hole. Thus dilution alloying has a much enhanced effect on magnetic ordering. The actual LDA calculations for dilution alloying have been carried out using supercells containing four uranium/lanthanum sites and four anion sites. Thus, at present, we can predict alloying effects only at intervals of 25% dilution.

III. RESULTS AND DISCUSSION

The predicted variation of Curie temperature with pressure and dilution alloying is compared to experiment^{3,5} for US in Fig. 1. We emphasize that the predictions are absolute. All input information is *ab initio* except for the baseline specification of the fraction of stable f^3 uranium for unalloyed US at atmospheric pressure. In Fig. 2, we show the comparison between the predicted and experimental⁵ low temperature ordered moment for $U_xLa_{1-x}S$. The remarkable agreement of prediction with experiment shown in Figs. 1 and 2, including the collapse of magnetic ordering somewhat above 50% uranium, provides strong confirmation of the correctness of the physical picture used. We have also calculated the predicted normalized ordered moment and Curie temperature behavior for diluted USe and UTe and reproduce the experimentally observed⁶ trend. For the baseline f^3 fractions used (0.50, 0.67, and 0.80 for US, USe, and UTe, respectively), the predicted Curie temperature and ordered moment are 183 K and $1.64 \mu_B$ (experimentally 180 K and $1.6 \mu_B$) for US, 149 K and $2.19 \mu_B$ (experimentally 160 K

FIG. 2. Calculated low-temperature ordered moment per uranium compared to experiment (from Ref. 5) for $U_xLa_{1-x}S$.

and $2.0 \mu_B$) for USe, and 91 K and $2.6 \mu_B$ (experimentally 104 K and $2.25 \mu_B$) for UTe. In addition find nonmonotonic variation of T_c for USe and UTe with pressure in excellent agreement with experiment.

In conclusion, we want to emphasize that the collapse of magnetic ordering in US is a catastrophic consequence of the existence of two kinds of occupied uranium, states and of the change in this mixture by increasing the f delocalization with pressure or dilution alloying. This picture is equivalent to that provided by the competing nonmagnetic and magnetic correlated ultranarrow band picture of Refs. 7–9 and contains all the essential physics of correlated f -electron behavior, including all aspects of heavy fermion behavior.

Electrical resistivity and ac magnetic susceptibility studies of the 5*f*-metamagnet UCoAl reveal the presence of strong spin fluctuation effects for temperatures below 30 K and magnetic fields below the critical metamagnetic field $\mu_0 H_c \approx 1$ T, where a non-Fermi liquid term $\sim T^{3/2}$ is prominent in the electrical resistivity. A step-wise increase of the residual resistivity and an increasingly prominent Fermi liquid T^2 term of the resistivity is observed as the field is increased through the metamagnetic transition. © 1998 American Institute of Physics. [S0021-8979(98)43411-X]

INTRODUCTION

UCoAl is a 5*f*-band metamagnet with a remarkably low critical magnetic field ($\mu_0 H_c \approx 1$ T). It crystallizes in the hexagonal ZrNiAl-type structure, which consists of alternating U-Co and U-Al layers stacked along the *c* axis. These structural features and hybridization between the uranium 5*f* and conduction electron states result in a strong uniaxial anisotropy with the easy-magnetization axis along the (001) direction.¹ A lack of anomalies in specific heat and resistivity¹⁻³ suggests that UCoAl has a nonmagnetic ground state. The temperature dependence of the magnetic susceptibility for the applied field along the *c* axis exhibits a broad maximum near $T = 17$ K.^{2,4} A weak spontaneous magnetization of the order of $0.01 \mu_B/\text{U}$ is observed below $T \approx 15$ K, especially for samples with a slight excess of Co.⁴ The absence of magnetic order at low fields is corroborated by a μ^+ -SR experiment.⁵ The 5*f* origin of the field-induced magnetization (about $0.3 \mu_B/\text{U}$) was demonstrated in polarized neutron diffraction experiments.^{6,7}

Previously, only polycrystalline resistivity data were available for UCoAl,^{2,3,8} although the strong anisotropy of the transport properties of UTX compounds requires experiments on single crystals to deduce basic characteristics of the low temperature behavior.

Because the crystal structure of UCoAl allows some off-stoichiometry and a Co excess apparently affects magnetic properties at low temperatures, we investigated two Co-deficient single crystals $\text{UCo}_{1-x}\text{Al}_{1+x}$ of slightly different compositions ($x = 0.05$ and 0.10), which were prepared by a mineralization method.⁴ The transport and magnetic behavior of these two compositions are quite similar.

Here we present the first results of electrical resistivity measurement with magnetic field up to 5 T and electrical current both applied along the *c* axis.

RESULTS AND DISCUSSION

Figure 1 shows the metamagnetic transition of

$\text{UCo}_{0.90}\text{Al}_{1.10}$ and its shift towards higher fields with increasing T . The data for $\text{UCo}_{0.95}\text{Al}_{1.05}$ are similar, but exhibit a slightly lower critical field H_c . Corresponding susceptibility χ (M/H vs T) data are displayed in Fig. 2. The data for $\mu_0 H = 0.5$ T are representative of the low-field region. Note that for $\mu_0 H = 2$ T, the $\chi(T)$ dependence resembles that of a ferromagnet. A magnetic field $\mu_0 H = 1$ T is sufficient to induce the metamagnetic transition below $T \approx 5$ K. The increase of H_c with increasing T is the reason why the sample reverts to the low-field state for higher temperatures.

General features of resistivity are similar for both compositions, although the residual resistivity ρ_0 is somewhat lower for $\text{UCo}_{0.95}\text{Al}_{1.05}$ (Figs. 3 and 4). $\rho(T)$ gradually saturates at high T , which is characteristic of spin-fluctuation materials such as USn_3 or UAL_2 .⁹

A prominent feature of the low temperature resistivity is a $T^{3/2}$ term that is present up to 17 K. This behavior is distinct from a Fermi-liquid T^2 dependence, which is expected for electron quasiparticle scattering. The upper limit of the

FIG. 1. Field dependence of magnetization M for the single crystal $\text{UCo}_{0.90}\text{Al}_{1.10}$ with field $H \parallel c$ axis at various temperatures T . The data for $T < 4.2$ K show a weak hysteresis. The arrows indicate the direction of the field sweep for $T = 1.8$ K. (After Ref. 4).

^{a)}Electronic mail: havela@apollo.karlov.mff.cuni.cz

FIG. 2. Temperature dependence of M/H measured in several fields $H||c$ for the single crystal $\text{UCo}_{0.90}\text{Al}_{1.10}$.

$T^{3/2}$ law is dependent upon magnetic field, and coincides with the onset of a strong low-temperature upturn in the dc magnetic susceptibility (see Fig. 2 for $\mu_0 H = 1$ T).

The $T^{3/2}$ law is predicted¹⁰ for a system with strong spin fluctuations due to incipient magnetic order. The extent of the $T^{3/2}$ region is gradually reduced as the applied field approaches H_c , and a knee develops near 10 K for $\mu_0 H \approx 1$ T. This knee broadens and slowly moves to higher temperatures when the magnetic field is increased above 1 T, and roughly follows the temperature dependence of $H_c(T)$. The Fermi liquid aT^2 dominates $\rho(T)$ for high fields and lower temperatures up to about 10 K; but in the range 10–30 K (above the knee) $\rho(T)$ is still best described by a $T^{3/2}$ dependence. It is noteworthy that the evolution of $\rho(T)$ with field is remarkably similar to comparable data¹¹ for weak ferromagnets like Sc_3In and ZrZn_2 .

A Quantum Design (SQUID) magnetometer was used to measure the ac susceptibility at various ac frequencies $0 \leq f \leq 1$ kHz and driving fields $0.01 \leq h_0 \leq 3.9$ Oe. Data for both the real [$\chi'(T)$] and imaginary [$\chi''(T)$] parts of the ac mag-

FIG. 3. Temperature dependence of electrical resistivity ρ (current i along the c axis) for $\text{UCo}_{0.95}\text{Al}_{1.05}$ single crystal in zero magnetic field. The inset shows the low temperature detail as well as the fits to $\rho \sim bT^{3/2}$ and $\rho \sim aT^2$, the latter yielding somewhat lower ρ_0 .

FIG. 4. Temperature dependencies of resistivity ρ for $\text{UCo}_{0.95}\text{Al}_{1.05}$ in various fields. The dotted lines represent the fits to the T^2 law, the full lines fits to the $T^{3/2}$ law. Note two different ρ scales (left and right).

netic susceptibility of $\text{UCo}_{0.95}\text{Al}_{1.05}$ ($\text{UCo}_{0.90}\text{Al}_{1.10}$ is analogous) are shown in Fig. 6. $\chi'(T)$ exhibits a broad maximum at $T \approx 16$ K in zero field, similar to the dc susceptibility. At magnetic fields just below H_c , a second, sharper peak appears and grows near 7 K, and is most pronounced at $\mu_0 H \approx 0.7$ T for $\text{UCo}_{0.95}\text{Al}_{1.05}$, and at $\mu_0 H \approx 1$ T for $\text{UCo}_{0.90}\text{Al}_{1.10}$. This feature is undoubtedly connected with the rapid variation of the dc susceptibility in this temperature range; it is clear that both a broad anomaly (10–20 K) and a sharp upturn (7 K) are visible in the dc susceptibility for $\mu_0 H = 1$ T, as seen in Fig. 2. Further increase of field leads to a broadening, and an apparent shift of the second peak to higher temperatures make a separation of the two anomalies

FIG. 5. Field dependence of resistivity ρ for $\text{UCo}_{0.95}\text{Al}_{1.05}$ at various temperatures. The lines are guides to the eye.

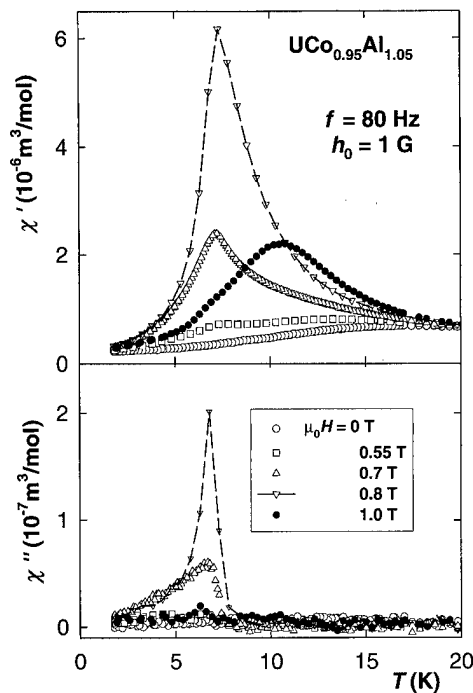

FIG. 6. Temperature dependencies of real χ' and imaginary χ'' parts of the ac susceptibility for $\text{UCo}_{0.95}\text{Al}_{1.05}$ at various static external fields. The line is the guide to the eye.

difficult. $\chi''(T)$ exhibits a narrow peak coinciding with the more prominent maxima in $\chi'(T)$, possibly reflecting the skin effect (i.e., permeability) variations, and dissipation accompanying the hysteresis at lowest temperatures (shown in Fig. 1). The peak in $\chi''(T)$ abruptly terminates at $T \approx 7$ K, which may be interpreted as an upper limit of a first-order phase transition.

The character of the ac susceptibility data provides evidence against the existence of a spin-glass or cluster-glass ground state induced by crystallographic disorder, in which case one typically observes a low-field cusp in $\chi_{ac}(T)$ that broadens with moderate applied dc field.

The shift of the maximum in $\chi'(T)$ with increasing T is similar to the behavior of band metamagnets (such as YCo_2),¹² but is in clear contrast with the metamagnetic fields of typical antiferromagnets. The latter typically decrease with increasing T , reflecting a higher entropy in the metamagnetic state. Thermodynamic considerations, based on the Clausius–Clapeyron equation, show that the metamagnetic transition in UCoAl reduces the entropy of the system.

The occurrence of the $3/2$ resistivity exponent strongly suggests that the behavior of UCoAl at low temperatures is dominated by critical spin fluctuations attendant with incipient magnetic order. The magnitude of the resistivity coefficient b increases with applied field up to H_C . The suppression of critical fluctuations in the metamagnetic state removes the non-Fermi liquid temperature dependence in favor of the Fermi liquid aT^2 term, with an a value that decreases gradually with field.

As seen in Fig. 5, the residual resistivity ρ_0 jumps at the metamagnetic transition from 35 to 38 $\mu\Omega \text{ cm}$ for $\text{UCo}_{0.95}\text{Al}_{1.05}$ and can be associated with a decrease of density

of states at the Fermi level $N(E_F)$ due to a Fermi surface reconstruction accompanying the formation of the $5f$ moment. This change is actually smaller than expected, because the spin-orbit interaction should result in a very strong coupling of the U magnetic moments to the electronic structure.¹³

A decrease of the total density of states at the Fermi level $N(E_F)$ is consistent with the observed reduction of the Sommerfeld specific heat coefficient γ in the metamagnetic state (from 75 to 55 mJ/mol K^2),¹⁴ and can also reflect the suppression of spin fluctuations. However, using the Kadowaki–Woods¹⁵ relation between the resistivity coefficient a and γ^2 , we would expect a value of the a coefficient even lower than our observed $a \approx 0.03 \mu\Omega \text{ cm K}^{-2}$ in the high field state. This discrepancy could simply result from anisotropy of the T^2 term, which is under investigation.

CONCLUSIONS

The low temperature behavior of UCoAl is strongly influenced by critical spin fluctuations due to incipient magnetic ordering, as reflected by a $T^{3/2}$ dependence over approximately 1 decade of the low-temperature resistivity below the critical metamagnetic field. The spin fluctuations are suppressed when the material enters the high field regime above the metamagnetic transition, where a Fermi liquid T^2 behavior of the resistivity is recovered. The residual resistivity for current along the c axis exhibits a step-wise increase at the metamagnetic transition ascribed to a Fermi surface reconstruction.

Orthorhombic URhSi orders ferromagnetically below $T_c = 9.5$ K, with an ordered magnetic moment $\mu = 0.11\mu_B$ per U atom and has a relatively enhanced value of the specific heat $c_p/T = 186$ mJ/mol K². U-U atomic distances fall in a critical region around the Hill limit so that it is thought to be an itinerant magnet. Our present investigation includes: (i) preparation of high purity crystalline samples further analyzed by single crystal x-ray diffraction and magnetization measurements; (ii) band structure calculations performed with self-consistent full potential linearized Augmented plane wave method within the local density approximation; (iii) optical measurements at room and at low temperature over a large spectral range (2 meV–6 eV). As a result, the details of the crystal structure of URhSi have been refined with respect to previous measurements on powdered samples. The comparison of electronic structure calculations and optical results show: (a) a low mobility of free carriers and a large dielectric screening at the lowest frequencies, connected with excitation of f states hybridized with d states at the Fermi level; (b) smooth spectral features due to the huge number and density of states (the main contribution being due to occupied Rh d states). The whole amount of information obtained would suggest the presence of Kondo-like behavior in this compound, independently on the magnetic order. © 1998 American Institute of Physics. I. INTRODUCTION

Intermetallic ternary uranium alloys have been studied during the latest years due to their interesting interplay between magnetic and electronic structure. Both localized and itinerant magnetism have been observed in this class of compounds, often coexisting with heavy fermion properties.^{1–3} One of the most investigated material was URu₂Si₂ that is an itinerant antiferromagnet with heavy fermion properties.^{1,4,5} URhSi is a compound with orthorhombic structure apparently not too different from URu₂Si₂. On the other hand, URh₂Si₂ is a normal magnet with transition temperature and magnetic moment expected from a Curie Weiss behavior.⁶ The first characterization of the physical properties of URhSi has been performed by Prokes *et al.*⁷ Neutron diffraction experiment, electrical resistivity, magnetic susceptibility, and specific heat measurements evidenced a ferromagnetic transition at 9.5 K with a reduced magnetic moment of $0.11\mu_B$ and itinerant character.

Stimulated by the possible interplay of crystallographic structure and electronic bonding (there are two different U-U distances in the structure) we undertaken a thorough investigation of this compound. The results of crystallographic, magnetic, optical, and theoretical investigations are detailed below.

II. EXPERIMENT

Samples of about 2 grams each were prepared by direct synthesis of the elements (U depleted 99.8 wt % purity, Rh

99.9 wt % purity, and Si 99.999 wt % purity. The Rh metal was outgassed under dynamic vacuum for 5 h. at 800 °C.) pressed together in form of pellets and then melted in a semi-levitation high-frequency induction furnace on a water-cooled tantalum heart under an atmosphere of pure and dry argon. The samples were inverted and remelted three times to ensure complete homogenization and then slowly cooled to room temperature.

A metallographic examination showed that the samples were single phase, well crystallized, and compact with little grain separation (1% at most). The phase of URhSi was examined by single crystal and powder methods. Intensity data of a single crystal with dimensions $20 \times 50 \times 70 \mu\text{m}^3$ were collected with a CAD-4 diffractometer using graphite monochromated Mo $K\alpha$ radiation in the θ range 2–30°. A total of 1309 reflections measured in the ω - θ scan mode gave 352 independent reflections with $R_{\text{int}}(F_0^2) = 0.158$. Both spherical and semiempirical absorption corrections based on the azimuthal scan data of a top reflection were applied, with a linear absorption coefficient of 83.7 mm^{-1} and a ratio between maximum and minimum transmission factors of 3.5. Lattice constants were obtained from a diffractometer powder pattern, using Cu $K\alpha$ radiation and Si as an internal standard.

Refinement of 19 parameters was made with SHELXL-93,⁸ applying anisotropic displacement parameters and weights $w = 1/[\sigma(F_0^2) + (0.1293P)^2]$, where $P = (F_0^2 + 2F_c^2)/3$. The final agreement factors were $wR(F^2) = 0.169$ for all data and $R = 0.064$ for 245 reflections with

3.299(2)

$F_0 > 4\sigma(F_0)$. Interatomic distances for U atoms calculated by the program SEXIE⁹ are listed in Table I.

The phase, orthorhombic, space group Pnma, $a = 6.990(1)$ Å, $b = 4.114(1)$ Å, $c = 7.427(1)$ Å, resulted to be isotypic with TiNiSi. From magnetization measurements, performed at 4.2 K in a Faraday balance in magnetic fields up to 1 Tesla on randomly oriented crystals, a saturation value (at 1 Tesla) of $0.56 \mu_B/f.u.$ was obtained, in agreement with the results of Prokeš *et al.*⁷

The electronic properties for the paramagnetic phase of URhSi have been determined using the self-consistent full potential linearized augmented plane wave (FLAPW) method within local density approximation (LDA). The calculated total and partial density of states (DOS) are shown in Fig. 1. U- f states result to be placed just above the Fermi energy (E_F) mixed with U- d , Si- p and, particularly, with Rh- d states. Due to the well known failure of LDA in correctly reproducing exchange-correlation effects in strongly localized states as the f states, the real energy position of these states can be quite different. However, it should be pointed out that the major contribution to the DOS of the occupied states (from E_F down to about -6 eV, which is the energy region of interest) comes from the Rh d states (see Fig. 1), which are very well reproduced by LDA. Si- s and U- p states lie practically unhybridized well below E_F (-8 eV and -19 eV, respectively).

FIG. 1. Electronic density of states (DOS) as calculated by FLAPW+LDA in URhSi. (Top: total DOS; middle: partial U- f DOS; bottom: partial Rh- d DOS).

FIG. 2. Optical reflectivity of URhSi measured at room temperature (dashed line) and at 6 K (full line).

Near normal optical reflectance measurements were performed on a polycrystalline disk of material with a diameter of about 7 mm and 2 mm thick. The sample surface was optically polished with diamond powder of decreasing size down to $0.25 \mu\text{m}$. The shining surface so obtained is crossed by some fracture lines which, anyway, affect only a small fraction of the measured area. ellipsometric measurements (ellipsometry is almost unaffected by roughness, but it is very sensitive to oxidation) performed at several different angles of incidence in the spectral region between near infrared and ultraviolet (1.4–5 eV) confirmed that the residual roughness only slightly affects the optical results at energies above 3 eV. A thin oxide layer due to air exposure of the sample is probably present, but it practically does not affect the near normal reflectance, particularly in the infrared.

The measurements were performed over a very broad spectral range from 2 meV up to 6.5 eV, using a Fourier transform infrared spectrometer, equipped with a Si bolometer, and a high precision grating spectrometer in the UV-visible spectral region. In the medium- and far-infrared the sample was also put on the cold finger of a helium flow cryostat and measured at several different temperatures between 6 K and room temperature.

The spectra so obtained exhibit an almost structureless, monotonically decreasing reflectivity from far infrared to ultraviolet (Fig. 2). A smooth change of curvature occurs in the medium infrared whereas a small structure emerges around 20 meV by lowering the temperature.

Kramers–Kronig transformation was applied to the reflectivity data in order to obtain the dielectric function and the optical conductivity. A small correction of the reflectivity data above 3 eV and a common extrapolation of the data as ω^{-s} above 6.5 eV were introduced (s was chosen in such a way as to ensure the consistence with the ellipsometric results). At energies below 2 meV an extrapolation was obtained by the Hagens–Rubens relation $R = 1 - \sqrt{2\omega/\pi\sigma_{dc}}$, where σ_{dc} is the static conductivity of the material, and assuming a Drude like behavior of the free carrier.

FIG. 3. Optical conductivity of URhSi obtained by Kramers–Kronig analysis at room temperature (dashed line) and at 6 K (full line).

III. DISCUSSION

The structure determination of URhSi by single crystal methods confirms its isotypism with the ordered TiNiSi type, as already reported by Prokes *et al.*⁷ by neutron diffraction measurements. However, the lattice constants found in the present work are all smaller than those determined by neutron diffraction at 80 K. A slightly higher fraction of U and a slightly lower fraction of Rh in the sample were hypothesized by Prokes *et al.* for both improving the fit of the neutron diffraction spectrum and matching the electron microprobe analysis; that could be partially responsible for the higher values of the lattice constants. Examining the interatomic distances in URhSi we see that the U–U, U–Rh, and U–Si distances are always larger than the sum of the elemental radii, but this is probably due to a scarce transferability of the uranium radius from elemental to alloyed states.

Kramers–Kronig analysis yield to an optical conductivity showing a smooth maximum at about 0.2 eV followed by a shoulder around 1 eV and an almost linear decrease for increasing energies (Fig. 3).

The smoothness of the optical structures is usually related to disorder effects, but in our case it is actually consistent with the calculated band structure, being related to the almost constant and large DOS below the Fermi level produced by the *d* states. The huge number of levels involved in the electronic structure is therefore responsible for the structureless and continuous behavior of the optical conductivity. As a matter of fact, very peculiar features appear at the lowest frequencies, reminiscent of heavy fermion behavior: Below 0.2 eV the optical conductivity decreases for decreasing

frequencies down to a smooth minimum around 10 meV; below this energy Drude like behavior is present. Due to the lack of exact information of the static conductivity, and than the difficulty in calibrating the low energy extrapolation for Kramers–Kronig transformations, it has not been possible to assign a defined value for the plasma frequency ω_p . Anyway, optical values impose some constraints to the possible ω_p value which could be in the order of a few tenths of eV, even at room temperature. At low temperature the features are even more clear: a well defined structure emerges at 20 meV, the minimum at 10 meV is further depressed and heavy fermion Drude behavior with a low plasma frequency is necessarily growing up at the lowest frequencies. A prudent estimate gives a value of $\omega_p \approx 0.2$ eV. The comparison of such a value with the available data of specific heat⁷ yields to an effective mass of about $60m_e$, in the range of values observed in similar compounds.^{2,5}

It is interesting to notice that such a behavior is unaffected by the onset of magnetic order at 9.5 K, being observed both above and below such a temperature. Moreover, the low temperature features begin to emerge in the reflectivity spectra already at 120 K. On the other hand, since the ferromagnetic transition does not open any gap at the Fermi surface, no changes can be expected in the optical response.^{3,5} A similar behavior has been observed in $\text{URu}_{2-x}\text{Re}_x\text{Si}_2$, where, for increasing amount of Re content, the material pass from itinerant anti ferromagnetism to itinerant ferromagnetism.^{1,5}

In conclusion crystallographic parameters of URhSi have been exactly determined and heavy fermion behavior has been identified which is not affected by the magnetic transition.

Weighted minimum-norm source estimation of magnetoencephalography utilizing the temporal information of the measured dataSunao Iwaki^{a)} and Shoogo Ueno^{b)}*Department of Biomedical Engineering, University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, Japan*

The weighted minimum-norm estimation (wMNE) is a popular method to obtain the source distribution in the human brain from magneto- and electro-encephalographic measurements when detailed information about the generator profile is not available. We propose a method to reconstruct current distributions in the human brain based on the wMNE technique with the weighting factors defined by a simplified multiple signal classification (MUSIC) prescanning. In this method, in addition to the conventional depth normalization technique, weighting factors of the wMNE were determined by the cost values previously calculated by a simplified MUSIC scanning which contains the temporal information of the measured data. We performed computer simulations of this method and compared it with the conventional wMNE method. The results show that the proposed method is effective for the reconstruction of the current distributions from noisy data. © 1998 American Institute of Physics. [S0021-8979(98)38511-4]

I. INTRODUCTION

Sophisticated techniques to provide functional imaging of information processing in the human brain are needed for clinical applications and for tools of investigation of higher brain functions. Many methods have been developed to reconstruct the internal electrical current distributions in the human brain from magneto- and electro-encephalographic (MEG/EEG) measurements.¹ Among those, the minimum-norm estimation (MNE)^{2,3} is a popular technique to obtain the internal primary current distributions if the detailed information about the generator profile was not available. Because the sensitivity of the sensors decreases as the distance from the source increases, the MNE tends to introduce a bias towards superficial sources.⁴ To avoid this problem, the weighted MNE (wMNE) method, which minimizes the weighted norm of the solution (depth normalization), has been widely applied.^{4,5} However, because the conventional wMNE method deals with only the instantaneous distribution of MEG/EEG data, reconstructed currents could be seriously distorted when the method is applied to noisy data. To reduce the distortion of the reconstructed current distribution, a method to include temporal information of the MEG/EEG data into the wMNE method using simplified multiple signal classification (MUSIC)⁶ prescanning is proposed in this article.

II. METHODS**A. Weighted minimum norm estimation**

Here, we define the primary current distribution at time instant t_i as $\mathbf{p}(t_i) = [\mathbf{p}_1(t_i), \mathbf{p}_2(t_i), \dots, \mathbf{p}_N(t_i)]^T$ and the measured field distribution as $\mathbf{f}(t_i) = [\mathbf{f}_1(t_i), \mathbf{f}_2(t_i), \dots, \mathbf{f}_M(t_i)]^T$, where N is the number of possible current source locations and M is the number of sensors. The relationship between \mathbf{f} and \mathbf{p} is described as

$$\mathbf{f} = L\mathbf{p} + \mathbf{n}, \quad (1)$$

where L is a gain matrix called the lead field matrix and \mathbf{n} is the additive measurement noise. The conventional wMNE method can be written as follows.⁷

$$\mathbf{p} = L^{-}\mathbf{f}, \quad (2)$$

where L^{-} is given by

$$L^{-} = (L^T L + \gamma \mathbf{W}_c)^{-1} L^T, \quad (3)$$

which minimizes the cost $E_c = \|\mathbf{f} - \mathbf{f}_c\|^2 + \gamma^2 \|\mathbf{W}_c \mathbf{p}\|^2$, (\mathbf{f}_c : calculated value of field distribution).⁷ The diagonal matrix \mathbf{W}_c contains the weighting factors for depth normalization, and γ is a regularization parameter, which controls the degree of regularization, determined in accordance with the signal-to-noise ratio (SNR). In this article, we use the simplest weighting factors for depth normalization ($\mathbf{W}_c = \text{diag}\{\|L_i\|_2\}$).

B. Weighted minimum norm estimation with MUSIC prescanning

Because the conventional wMNE method deals with only instantaneous distributions of MEG/EEG data, results of current reconstruction could be seriously distorted when

^{a)}Electronic mail: iwaki@medes.m.u-tokyo.ac.jp

^{b)}Electronic mail: ueno@medes.m.u-tokyo.ac.jp

FIG. 1. Assumed source locations for the computer simulations. Two dipolar current sources were located at $(-0.2R, -0.2R, 0.7R)$ and $(0.2R, 0.2R, 0.7R)$.

applied to noisy (low SNR) data. To reduce the distortion of the reconstructed current distributions, we propose a method to include temporal information in the wMNE using simplified MUSIC prescanning.

First, to separate signal and noise subspaces of $M \times l$ spatio-temporal measured data matrix $\mathbf{F} = [\mathbf{f}(t_1), \mathbf{f}(t_2), \dots, \mathbf{f}(t_l)]$ using an eigen-decomposition of the auto-correlation matrix of \mathbf{F} . Here, we denote Λ_s, Λ_n as a diagonal matrix containing signal and noise eigenvalues, and Φ_s, Φ_n as signal and noise eigenvectors, respectively. Then, for each scanning grid j located in the head model, we calculate the cost values c_j ,

$$c_j = 1/\lambda_{\min}\{\mathbf{U}_{Lj}^T \Phi_n \Phi_n^T \mathbf{U}_{Lj}\}, \quad (4)$$

where $\lambda_{\min}\{\cdot\}$ denotes the minimum eigenvalue of $\{\cdot\}$, and \mathbf{U}_{Lj} denotes the principal left eigenvector of L_j . Then c_j becomes 0 at the correct source location when the source is modeled as a single current dipole,⁸ and c_j approximates the relative values of time-averaged current intensity if the source can be modeled as a few current dipoles.⁹

We use the cost values c_j to determine the weighting factors of wMNE as follows.

$$\mathbf{W} = \mathbf{W}_c + \mathbf{W}_m = \text{diag}\{\|\mathbf{L}_i\|_2\} + \alpha \text{diag}\{I - \tilde{c}_j\}, \quad (5)$$

$$\mathbf{L}^- = (\mathbf{L}^T \mathbf{L} + \gamma \mathbf{W})^{-1} \mathbf{L}^T, \quad (6)$$

where \tilde{c}_j is a normalized value of c_j , and α is a alteration parameter of weighting factors. This method minimizes the cost $E_m = \|\mathbf{f} - \mathbf{f}_c\|^2 + \gamma^2 \|(\mathbf{W}_c + \mathbf{W}_m)\mathbf{p}\|^2$ that causes the reconstructed current distribution to be biased towards the regions with the largest c_j values calculated by the simplified MUSIC prescanning. When $\alpha=0$, the proposed method becomes identical to the conventional wMNE method.

FIG. 2. Example of the spatial distribution of the MEG. The SNR of the simulated data was set to 4 dB.

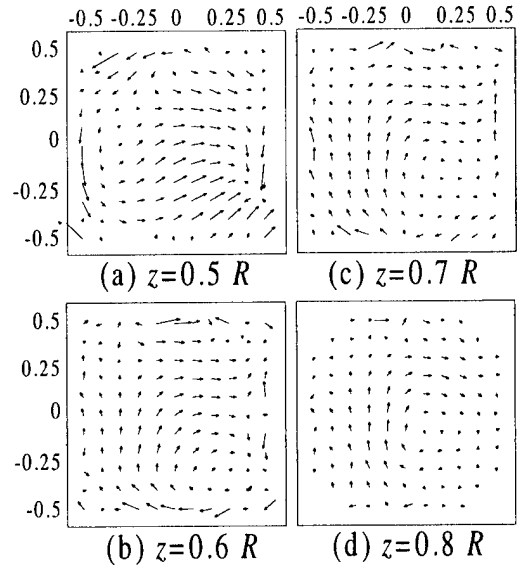

FIG. 3. Results of current reconstruction using the conventional wMNE method. Axial views of the reconstructed current distributions in the x - y plane are displayed with (a) $z=0.5R$, (b) $z=0.6R$, (c) $z=0.7R$, and (d) $z=0.8R$. The SNR of the simulated data was 4 dB, and the regularization parameter γ was set to 0.4.

This method utilizes not only the instantaneous spatial distribution but also the temporal properties of the measured data. It is possible to reconstruct current distribution properly even if the SNR of the measured data were so low that the conventional wMNE method might fail to reconstruct.

III. RESULTS AND DISCUSSION

We performed computer simulations of the proposed method and compared the results with the results from the conventional wMNE method.

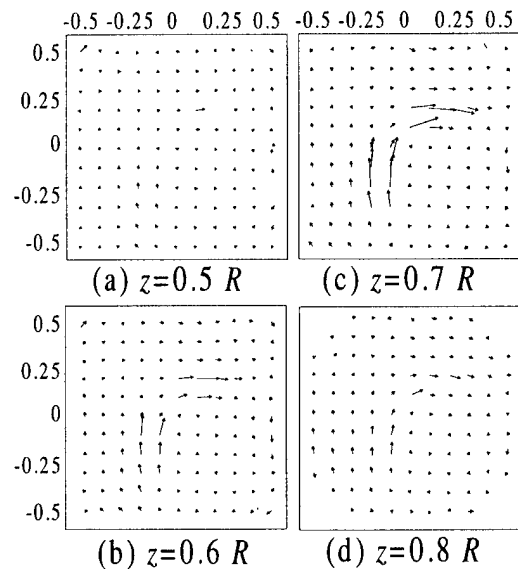

FIG. 4. Results of current reconstruction using the proposed method. Axial views of the reconstructed current distributions in the x - y plane are displayed with (a) $z=0.5R$, (b) $z=0.6R$, (c) $z=0.7R$, and (d) $z=0.8R$. The SNR and γ were the same as for Fig. 3, and the alteration parameter α was set to 0.06.

Figure 1 shows an assumed source configuration for these simulations. Two current dipoles were located in the x - y plane [(a) $(x,y,z)=(-0.2R,-0.2R,0.7R)$, (b) $(x,y,z)=(0.2R,0.2R,0.7R)$, R : radius of the head model]. The y component of the assumed source (a) and the x component of the source (b) were assumed to alter synchronously. Magnetic fields generated by these sources were assumed to be measured at 80 points on the upper hemisphere of the head model, and white noise was added. The SNR of the simulated data was approximately 4 dB, which was relatively low when compared with actual MEG measurements of large evoked responses with an adequate number of signals averaged. However, the SNR was not low when compared with that of spontaneous brain activities without averaging or evoked responses with a limited number of data sets. An example of the instantaneous spatial distribution of simulated data is shown in Fig. 2.

The results of the current reconstruction using the conventional wMNE method and the proposed method are shown in Fig. 3 and Fig. 4, respectively. In each figure, axial views of reconstructed current distributions in the x - y plane are displayed with (a) $z=0.5R$, (b) $z=0.6R$, (c) $z=0.7R$, and (d) $z=0.8R$. In these simulations, the regularization parameter γ and alteration parameter α were set to $\gamma=0.4$, $\alpha=0.06$ empirically. The reconstructed current distribution was severely distorted in the conventional wMNE method under noisy measurement condition as SNR equals to 4 dB. In the proposed method, current distributions corresponding to two assumed sources were clearly reconstructed. These results indicated the effectiveness of the proposed method for the reconstruction of internal current distributions under the noisy measurement condition. In these cases, the increase of the amount of calculation in the proposed method was less than 10% of that required in the conventional wMNE method.

Further consideration must be given to develop algorithms to obtain optimum values of the regularization and alteration parameters.

IV. CONCLUSION

We proposed a method to reconstruct current distributions in the human brain based on the weighted minimum-norm estimation technique with the weighting factors defined by simplified MUSIC prescanning. With this method, in addition to the conventional depth normalization technique, weighting factors of the wMNE were determined by the cost values previously calculated by simplified MUSIC scanning which contains the temporal information of the measured data. We performed computer simulations of this method and compared it with the conventional wMNE method. The results show that the proposed method is effective for the reconstruction of the current distributions from noisy data.

A comparative study of the magnetic separation characteristics of magnetotactic and sulphate reducing bacteria

A. S. Bahaj,^{a)} P. A. B. James, and F. D. Moeschler

University of Southampton, Southampton, Hampshire, SO17 1BJ, United Kingdom

Many microorganisms have an affinity to accumulate metal ions onto their surfaces which results in metal loading of the biomass. Microbial biomineralization of iron results in a biomass which is often highly magnetic and can be separated from water systems by the application of a magnetic field. This article reports on the magnetic separation of biomass containing microbial iron oxide (Fe_3O_4 , present within *magnetotactic* bacteria) and iron sulphide (Fe_{1-x}S , precipitated extracellularly by sulphate reducing bacteria) in a single wire cell. Since such bacteria can be separated magnetically, their affinity to heavy metal or organic material accumulation render them useful for the removal of pollutants from waste water. The relative merits of each bacterium to magnetic separation techniques in terms of applied magnetic field and processing conditions are discussed. © 1998 American Institute of Physics. [S0021-8979(98)38611-9]

I. INTRODUCTION

Magnetotactic bacteria (MTB)¹ which biomineralize magnetite (Fe_3O_4) and sulphate reducing bacteria (SRB) present within sediments, contrast in their utilization of iron which is based on the oxide and sulphide forms, respectively. A magnetotactic spirillum and a sulphate reducing vibroid have been isolated from brackish sediments near Southampton, UK and grown in pure culture. The MTB possess a magnetic moment along their line of length due to a chain of membrane enveloped magnetite crystals called *magnetosomes*. Transmission electron microscopy utilizing electron dispersive x-ray analysis confirmed that the magnetosomes within Southampton MTB were iron oxide based. This magnetite chain acts as a dipole, enabling magnetic orientation of the bacteria with the earth's magnetic field (magnetotaxis). This results in flagellar driven motion downwards towards the oxic-anoxic transition near the sediment-water interface of their salt marsh pan environment.

Unlike magnetotactic bacteria, sulphate reducing bacteria do not, in general, exhibit magnetotaxis. Ferrous (Fe^{2+}) and ferric (Fe^{3+}) sulphate ions are taken up by SRB in a process known as "dissimilatory sulphate reduction" where the sulphate ions act as an oxidizing agent for the dissimilation of organic matter, as oxygen does in conventional respiration.² A small amount of the reduced sulphur is assimilated by the organism, and the iron ions are then precipitated onto the bacterium surface. In a magnetic field, this coating gives rise to a randomly orientated magnetic dipole, as opposed to the specific direction of the permanent dipole found in MTB.

Recently, a sulphate reducing bacterium has been discovered which is magnetotactic, containing intracellular magnetosomes of magnetite and extracellular iron sulphide precipitation.³ Moreover, magnetotactic bacteria which form magnetosomes of iron sulphide, such as greigite (Fe_3S_4) and pyrite (FeS_2) have been found.⁴ It must be remembered

therefore, that the relationship between iron sulphide/oxide and sulphate reducing/magnetotactic bacteria is not as clear cut as considered here.

Many microorganisms have an affinity to accumulate metal ions into their surfaces which results in metal-loading of the biomass. Hence water systems can be purged of metal pollutants when the biomass is removed. This article reports on the separation approach for removing the loaded biomass from a metal polluted system. In the case of magnetotactic bacteria there are two conditions for separation: Case (a) represents the removal of *motile* MTB and the utilization of their magnetotaxis property. In this case orientational magnetic separation can be applied where direction of motion is imposed externally whilst the motion is due to the flagella effect of the bacteria. Case (b) applies to the removal of *non motile* MTB as well as the sulphate reducing bacteria using high gradient magnetic separation (HGMS). The article also discusses the various conditions under which each type of bacteria can be utilized for enhanced magnetic separation processes.

II. EXPERIMENT

The experimental setup for single wire cell studies consists of a dedicated analysis workstation coupled to an optical microscope. On the microscope stage is mounted a small iron yoke to which pairs of boron-iron-niodymium magnets are attached. Between the magnets is placed a glass cuvette containing an 8.3 μm nickel wire. The wire is aligned perpendicular to the magnetic field, producing magnetic gradients up to 10^{10} Tm^{-1} , enabling capture of magnetic material from the surrounding medium. A sample of MTB or SRB is added to the cuvette and a recording of the resulting motion is made onto a VCR for subsequent analysis. A specialized hardware/software package enables sampling of the VCR recording to generate a sequence of frames marking the position and time of a cell as it is captured onto the wire.⁵

Magnetotactic bacteria were grown in 100 ml batch cultures incubated at 30 °C for ten days using standard magnetospirillum growth medium.⁶ Single wire cell measure-

^{a)}Electronic mail: bahaj@soton.ac.uk

ments were made on individual motile and nonmotile bacteria. To render MTB nonmotile specific metal ions were added to a culture 15 min prior to addition to the single wire cell.

Sulphate reducing bacteria were grown at room temperature in a 2 ℓ chemostat, operated at a dilution rate of 0.028 through which nitrogen was bubbled to maintain anaerobic conditions and provide mixing. The medium used was a development of a Freke and Tate preparation for the culture of sulphate reducing bacteria from soil.⁷ Single wire cell measurement of the motion of disordered "clumps" of iron sulphide rich biomass, ranging in size from 1.6 to 12 μm across, were made.

To observe particle motion, small volumes of biomass were pipetted into a cuvette which was half filled with distilled water. Single wire cell measurement of the motion of disordered clumps of iron sulphide rich biomass, ranging in size from 1.6 to 12 μm across, were made.

To observe cell motion, small volumes of biomass were pipetted into a cuvette which was half filled with distilled water. Measurements were made in effectively no flow conditions (quasistatic). Single wire cell experiments were carried out at three different magnetic field strengths (0.110 T, 0.284 T, and 0.688 T). In each case the motion of 50 MTB was analyzed to produce an average capture profile of a bacterium onto the wire.

The experimental conditions used allowed for cells up to an initial distance of 9 wire diameters (70 μm from the wire) to be imaged. The width of the imaging area being determined by the magnification of the camera/microscope system. The capture limit of several iron sulphide rich SRB was found to be in excess of 70 μm at 0.110 T. The magnification of the microscope was therefore halved, and single wire cell capture repeated at both 0.110 T and 0.284 T enabling capture profiles at much greater distances to be studied (18 wire diameters, 150 μm). At both field strengths the capture below 70 μm produces average paths which are independent of the microscope magnification used. The average capture paths shown for the SRB are therefore, the result of two sets of 50 profiles at different magnifications. Measurements on iron sulphide rich biomass were made at the two lower fields. At 0.688 T the high speed of cell-field interaction made accurate measurement ineffective.

III. RESULTS AND DISCUSSION

A typical magnetotactic bacterium studied here was found to have the following characteristics: length=2.9 μm , width=0.6 μm , determined using transmission electron microscope techniques—number of magnetosomes=15, diameter=30 nm.

The results depicted in Fig. 1 illustrate a comparison of high gradient magnetic separation, in a single wire cell, of motile magnetotactic bacteria and iron sulphide rich SRB biomass. The curves show the paths of the cells as they approach the wire in the cell and represent the average of 50 trajectories for MTB and 100 trajectories in the case of SRB.

The capture of motile MTB was found to be effectively independent of the applied magnetic field at distances greater

FIG. 1. Comparison of high gradient magnetic separation, in a single wire cell. Motile magnetotactic bacteria average trajectory; (a) 0.284 T and iron sulphide rich SRB biomass trajectories, (b) 0.284 T and (c) 0.110 T are shown.

than several wire diameters from the center of the wire. Away from the close proximity of the wire the flagellar force dominates over the magnetic field force producing an effectively linear capture profile. For the current experimental setup, it can be seen from the results that a cross-over point occurs in which the capture of iron sulphide rich SRB is more effective than MTB. For example, at 0.284 T, for cells initially, less than 7.2 wire diameters (60 μm from the wire) SRB material will be captured more rapidly. Furthermore, the point at which this cross-over occurs increases in distance from the wire as the applied magnetic field is increased.

Figure 2 shows the average capture profiles of 50 non-motile MTB and iron sulphide rich SRB at a various applied

FIG. 2. High gradient magnetic separation of iron sulphide rich SRB biomass; (a) 0.284 T, (b) 0.110 T and nonmotile magnetotactic bacteria, (c) 0.688 T, (d) 0.284 T, (e) 0.110 T. Graph depicts the average trajectories of 50 MTB and 100 SRB.

magnetic fields. Previously⁸ the magnetic moment of MTB was estimated from analysis of the trajectories of nonmotile bacteria using single wire theory.⁹ The analysis is repeated for this work and gives an average bacterium magnetic moment of $1.1 \times 10^{-15} \text{ Am}^2$, similar to that obtained previously. Determination of the magnetic moment of the disordered structure of the SRB material is rather complex and is not undertaken under this study. However, for this case, the results give a clear indication of the separation profiles that are likely to occur. It can be seen that at 0.284 T for example, the capture range of nonmotile MTB (less than four wire diameters) is less than the SRB material at 0.110 T (more than nine wire diameters). MTB are first orientated by the field, to give an "end-on" alignment trajectory of capture onto the wire. Despite the drag minimization that results from this alignment, the randomly orientated SRB material is captured at higher speed or more efficiently, indicating its significantly higher magnetic moment.

Motile magnetotactic bacteria, which are magnetically orientated by the applied field to swim in a required direction, can offer a pragmatic processing alternative. Motile MTB recovery is a relatively slow process. A typical bacterium swims at approximately $40 \mu\text{ms}^{-1}$, the separation time of bacteria from a wire mesh matrix is dependant only on the distance to the nearest suitably magnetized site. Therefore, for an efficient separation, it is necessary to process such MTB in a system where the site proximity is close to the bacterium which would minimize time of travel and hence the residence time.

Another approach is to separate motile MTB using magnetic poles positioned around a separation chamber. MTB accumulate at the north and south magnetic foci on the separation chamber walls for subsequent recovery from the system. This process when applied to metal/organic recovery will require static treatment chambers or slow moving waste streams of bacteria leading to long processing times. This contrasts with HGMS recovery of SRB material which, with suitable matrix, flow and field conditions rapid separation

can be achieved. The only penalty with HGMS being the moderately high magnetic field that is required (1–2 T for most conditions).

IV. CONCLUSIONS

This study depicts aspects of magnetic separation techniques applied to two distinct microbial systems. The single wire cell work illustrates that the magnetic iron sulphide coating present on SRB enables efficient separation using HGMS. The magnetic interaction of nonmotile MTB is weak in comparison to SRB. Despite the minimized drag effect of magnetically aligned, end-on capture, high gradient capture of nonmotile MTB was shown to be less effective when compared with SRB recovery regardless of the conditions used.

In contrast, orientation magnetic separation of MTB provides a simpler approach which can potentially be integrated into the process circuit of numerous processes (e.g., nuclear power stations, tanning plants, steel works, etc.). In this way contamination can be removed prior to discharge producing a truly "clean" technology. The separation conditions for a process have been well defined but significant metal/organic loading and continued viability of the biomass under a sufficiently wide variety of conditions has yet to be achieved.

Department of Chemistry, Trinity College, Dublin 2, Ireland

The effect of a uniform static magnetic field on processes occurring at Cu/acidified CuSO₄ interfaces is examined by analysis of potentiodynamic polarization curves. The mass transport controlled deposition current is increased by as much as a factor of 2 in a 0.6 T field, independent of field direction and electrode orientation. The extent of current enhancement is greatest at low *pH* (<1), where it is associated with diffusional rather than migrational transport of the copper ions.

I. INTRODUCTION

The processes of electrochemical metal deposition and dissolution¹ are of fundamental scientific and technological interest. They involve interfacial electron transfer which is strongly influenced by the magnitude of the electric field present at the electrode/solution interface. The rates of metal deposition/electrodissolution may be expressed in terms of current densities and kinetics quantified by analysis of steady state current/voltage curves, with recourse to phenomenological electrode kinetic models. Heterogeneous electrochemical processes involve, in general, two coupled sequential processes: diffusional mass transport to the surface of the electrode and potential-induced interfacial electron transfer between an electron donor/acceptor species in the solution and the electrode surface. Either interfacial electron transfer (activation control) or reactant logistics (mass transfer control) can be rate determining. For a sequential electrochemical process involving the transfer of a single electron, the steady state current density is given by²

$$j = \frac{Fk_E k_D c^\infty}{k_E + k_D}, \quad (1)$$

where *F* is the Faraday constant, *k_E* is the heterogeneous electrochemical rate constant, *k_D* is the diffusional rate constant, and *c[∞]* represents the concentration of electroactive reactant species in the bulk solution. If we utilize the Nernst diffusion layer approximation³ the diffusional rate constant *k_D* is given by *D/δ*, where *D* is the diffusion coefficient of the reactant and *δ* denotes the diffusion layer thickness. Also the heterogeneous electron transfer rate constant is given by the Butler-Volmer equation:

$$k_E = k_E^0 \exp(\pm \alpha \theta), \quad (2)$$

where *k_E⁰* denotes a potential independent rate constant and *α* is the transfer coefficient. Note that *θ* is a normalized potential and is related to the Galvanic potential drop *Δψ* across the electrode/solution interface by *θ* = *FΔψ/RT*, where *R* is the gas constant.

Clearly when *k_E* ≫ *D/δ*, the electron transfer kinetics are rapid and the electron transfer current will be controlled by the rate of mass transport to the electrode surface. Under such circumstances Eq. (1) reduces to

$$j = \frac{FDc^\infty}{\delta}. \quad (3)$$

In contrast when *k_E* ≪ *D/δ*, the rate of reactant supply is rapid and the electron transfer kinetics are slow and the reaction is activation controlled. Here Eq. (1) reduces to

$$j = Fk_E^0 c^\infty \exp\left(\pm \frac{\alpha F \Delta \psi}{RT}\right). \quad (4)$$

There are few well-documented examples of uniform static magnetic fields influencing the rates of chemical reactions, although there have been several previous reports of a field effect on the electrodeposition of copper.^{4,5} The effect of an applied magnetic field on a heterogeneous electrochemical process at an electrode/solution interface is termed magnetoelectrolysis. The applied *B* field might effect the transport of reactants to the electrode surface,⁴ accelerate the electron transfer kinetics at the electrode/solution interface,⁶ or indeed modify the transport rate of solvated ions in the bulk electrolytic solution.⁷ Here we focus on the effect of magnetic fields on reactant species located in regions close to the electrode surface, with specific reference to copper electrodes in contact with acidified copper sulfate solutions.^{5,8}

II. EXPERIMENTAL METHODS

All experiments were performed in a standard one compartment three electrode cell containing an Ag/AgCl (satd. KCl) reference electrode, a large surface area graphite counter electrode and a copper working electrode. The copper electrode was constructed by spot welding a copper wire to a copper plate (thickness 1 mm) of geometric surface area 85 mm². The wire was encased in a glass tube and the sides and rear surface of the copper plate electrode were sealed with epoxy. The electrode was polished before each experiment using fine grain sandpaper and then washed with 2 M sulfuric acid followed by thorough rinsing with triply distilled water. The electrochemical experiments were controlled using an EG&G Model 273 potentiostat. Potentiodynamic current/voltage curves were recorded using an XY plotter. A Magnetic Solutions Model HC600-54 Halbach cylinder with a 54 mm bore was used to apply a static magnetic field of magnitude 0.6 T to the electrochemical cell

FIG. 1. Tafel plot for copper sulfate in acidified aqueous solution at $pH = 0.8$ with (a) no external applied magnetic field, (b) an external applied field of 0.6 T.

which was placed centrally within the cylinder. In all experiments the electrolyte was an aqueous solution of 0.75 M copper (II) sulfate. The pH of the copper sulfate medium was varied by the addition of 2 M sulfuric acid. Solution pH values were measured using a digital pH meter.

III. RESULTS

The electrochemical behavior of the system was examined by applying a slow (10 mV s^{-1}) potential sweep to the copper electrode and examining the resultant current response profile. Typical potentiodynamic curves at $pH = 0.8$ with and without the field are presented in Fig. 1. The current response recorded at negative potentials corresponds to copper deposition and other reduction processes, whereas that obtained at positive potentials corresponds to electrodisolution of copper. The curves comprise a number of clearly defined regions. First we consider the cathodic portion. A narrow Tafel type region, where $\log j$ varies linearly with potential, may be identified at low negative potentials, from -200 to -100 mV . Here the electron transfer kinetics at the interface are slow and rate determining. It is seen from Fig. 1 that the magnetic field has some effect on the magnitude of the current response in the Tafel region. But the current plateau which extends from -200 to -900 mV increases very considerably when the field is present. This feature of curve can be ascribed to the diffusion controlled transport of aquo Cu^{2+} species to the electrode surface. The rise in current at potentials more cathodic than the current plateau region is due to the electroreduction of water to form molecular hydrogen. This process also remains unaffected by the imposition of a static magnetic field. The current response at anodic potentials is due to the electrodisolution of copper. The application of the field appears to have little effect here.

We have observed that the plateau of current enhancement due to the magnetic field depends to a marked extent on the pH of the solution. In Fig. 2(a) we show the variation of the mass transport controlled limiting current for copper electrodeposition in the absence and in the presence of the 0.6 T field, with changes in solution pH . Both the “field

FIG. 2. Current enhancement at -500 mV as a function of pH : (a) effect of external applied field, (b) percentage enhancement.

off” and “field on” currents increase with decreasing solution pH , but the enhancement increases markedly with decreasing pH , as shown in Fig. 2(b). The extent of current enhancement is typically 10–15% over the pH range 1.5–2.5, whereas a very rapid increase in current enhancement is observed when the solution becomes strongly acidic. For example, at pH 0.7 the current enhancement is 117%. This effect had not been noted previously in the literature. Furthermore, in a series of experiments where we varied the electrode orientation and field direction relative to the cell we could detect no significant variations, leading to the conclusion that the effect is independent of the direction of magnetic field.

The mass transfer enhancement induced by the magnetic field was confirmed by weighing the copper electrode. When the potential was held at -500 mV for a fixed interval at pH 0.8, 11 mg of copper was deposited when the magnetic field was applied compared to 5 mg with no applied field.

Figure 3 shows the Tafel plots obtained for the cathodic copper electrodeposition process at $pH = 0.72$. Plots of $\log j$ vs V are presented in Fig. 3(a). The curvature indicates that the potential region where deposition is kinetically controlled is quite narrow. Mass transport effects become important at quite low potentials. Hence we use the following modified form of the Tafel equation to extract values for the transfer coefficient α :

$$\log\left(\frac{j j_L}{j - j_L}\right) = K + \log c^\infty - \frac{\alpha F V}{2.303 R T}, \quad (5)$$

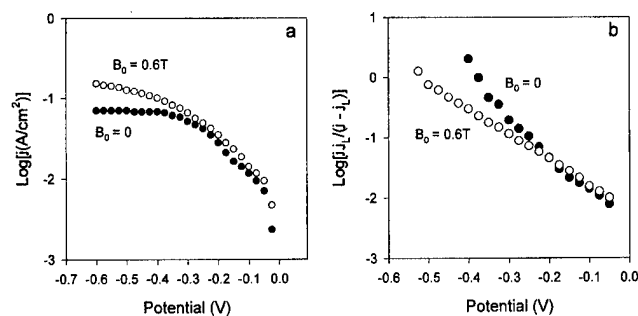

FIG. 3. (a) Tafel plot for copper sulfate in acidified aqueous solution at $pH = 0.72$. (b) Modified Tafel plot showing effect of the magnetic field on the transfer coefficient.

where j_L denotes the limiting plateau current density, j is the measured current density at any applied potential V . Modified Tafel plots presented in Fig. 3(b) are linear. The transfer coefficient α in the absence of a static magnetic field is 0.38, whereas in the presence of the 0.6 T field we obtain $\alpha = 0.24$. These values are lower than the theoretically expected value of 0.5. However, our current/voltage data have not been corrected for uncompensated solution IR errors which can be significant when large currents flow at the interface.

The value of the transfer coefficient α is an indicator of the copper deposition process. Our values are in good agreement with the mechanism proposed by Mattsson and Bockris.⁸ Hence we assign the following sequential mechanism:

The rate-determining step is the formation of an aquo $\text{Cu}(\text{I})$ species, which rapidly accepts a second electron to form metallic copper.

IV. DISCUSSION

It appears that the primary effect of the magnetic field is to alter the rate of transport of ions to the surface of the working electrode. The effect of magnetic fields on the kinetics of interfacial electron transfer processes (manifested as currents in the Tafel region of the potentiodynamic response curve) is relatively small. In addition to the entropic and viscous forces which control diffusion of hydrated ions in aqueous solution, electric and magnetic fields will generate a force on the electroactive ions which can be expressed in terms of the Lorentz equation:

$$\mathbf{F} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}), \quad (6)$$

where q denotes the charge on the ion and \mathbf{v} is the ionic velocity. The net magnetic force generated per unit volume \mathbf{F}_M is related to the net current density \mathbf{j} associated with ion transport through the solution by $\mathbf{F}_M = j\mathbf{B} \sin \theta$, where θ is the angle between the current vector and the field. Taking $j \sim 0.1 \text{ A cm}^{-2}$, we obtain $F_M \sim 600 \text{ N m}^{-3}$. We then compare this force to the gravitational force on the copper ions in the same volume, $F_G \sim 470 \text{ N m}^{-3}$, justifying the idea that the magnetic field might influence convection.

Striking features of our data are the independence of the current enhancement on the angle θ , and the pH dependence, with the sharp increase below a pH of 1.4. The Pourbaix diagram for the sulfur/water system at 298 K indicates that the predominant anionic species changes from SO_4^{2-} to HSO_4^- at a solution pH value close to 1.5.

Hence the composition of the ionic atmosphere surrounding the copper ion changes in this critical pH region. Furthermore, as the pH is reduced, the solution becomes more conducting, which reduces the electric field in the diffusion layer and cuts down transport of ions by direct migration to the cathode.⁹ The transport process at low pH is essentially diffusive, which means that the velocity to consider in Eq. (4) is the instantaneous velocity of the ion, rather than the velocity associated with the net current density. As a result, it is the effective diffusion coefficient D in the boundary layer, or possibly the thickness δ of the layer itself which is influenced by the magnetic field.

It has been noted in recent literature^{10,11} that the rate of transport of electrically neutral species can also be significantly enhanced by an applied magnetic field. Since the Lorentz force acting on a neutral species is zero, the field-induced enhancement of the flux of a neutral molecule must occur indirectly. One possibility is that experimentally observed current and material flux enhancement is due to convective solution flow induced by the field. This approach can be quantified in the context of magnetohydrodynamic theory.¹² Microscopically, the solution flow results from a momentum transfer from electric-field-accelerated ions to neighboring ions and solvent molecules. Hence, as noted by White and co-workers,^{10,11} the MHD analysis describes current enhancement in terms of a magnetic body force acting on a solution element through which a distributed and continuous current passes, rather than in terms of the direct interaction of the field on discrete current carrying ions.

Impedance magnetic resonance imaging: A method for imaging of impedance distributions based on magnetic resonance imaging

S. Ueno^{a)}

Department of Biomedical Engineering, Graduate School of Medicine, University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, Japan

N. Iriguchi

Siemens-Asahi Medical Technologies Limited, Tokyo 141, Japan

Magnetic resonance imaging (MRI) techniques have become important tools in medicine and biology. Conventional MRI, however, produces no information about the electrical properties of the body. This article proposes a new and noninvasive method for imaging electrical properties such as conductivity and impedance based on MRI techniques. The basic idea is to use the shielding effects of induced eddy currents in the body on spin precession. Two types of methods are introduced; (i) a large flip angle method, and (ii) a third coil method. The large flip angle method enhances the shielding effects of conducting tissues at the given Larmor frequency. The third coil method detects the shielding effects of conducting tissues at an arbitrary frequency. Both phantom and animal experiments have been carried out to verify this concept using a MRI system of 7.05 T with a bore size of 183 mm in diameter. © 1998 American Institute of Physics. [S0021-8979(98)23711-X]

I. INTRODUCTION

Since electrical properties are important characteristics of living organisms, techniques for impedance tomography to visualize impedance distribution have been developed with great interests.^{1,2} The previously proposed techniques require that electrodes are attached to the surface of the human body. Meanwhile, magnetic resonance imaging (MRI) techniques have become important tools in medicine and biology. Conventional MRI, however, produces no information about the electrical properties of the body. This article proposes new methods to visualize electrical impedance distribution based on MRI techniques.

When conductive tissues are subjected to an excitation rf field in MRI, eddy currents are induced in the tissues. In this article, a new method for impedance tomography is introduced based on MRI techniques. The basic idea is to use shielding effects of induced eddy currents in the body on spin precession. Two types of methods are proposed.

One proposed method to visualize the conductivity distribution of living organisms is to use very large flip angles. The method is used to obtain conductivity-enhanced MR images at the given Larmor frequency.

Another proposed method is to apply an additional time-varying magnetic field parallel to the main static field B_0 . The magnetic field is produced by the third coil, named “ B_c ” coil. The method is used to obtain conductivity-enhanced MR images at an arbitrary frequency. Experiments have been carried out to verify these concepts using a 7.05 T, 18.3 cm system.

II. PRINCIPLES

When conductive tissues are exposed to rf magnetic fields, eddy currents are induced in the conductive tissues,

which results in the reduction of the net rf fields into the tissues. By the shielding effects, the flip angles, (i.e., nutation angles of the macroscopic magnetization of excited spins from the axis of the main static field B_0 .) are reduced in varied degrees, depending on the electrical characteristics of the tissues.

When a precise 180° , 360° , or 540° excitation pulse is applied to conductive tissues, the tissues do not yield a signal due to the absence of the transversal components of magnetization. Meanwhile, resistive tissues yield signals because they are less electrically shielded than conducting tissues and simultaneously undergo different flip angles. Also, the resistive tissues leave transversal components with magnitudes determined by the sine wave functions of flip angles. The difference in signal, therefore, reflects the conductivity of tissues. By applying very large flip angles, conductivity-enhanced MR images can be obtained, yet, only at the given Larmor frequency, and in the direction perpendicular to the applied rf field.

To obtain conductivity-enhanced images at an arbitrary frequency, an additional time-varying field parallel to the main static field B_0 is introduced. The perturbing field is produced by the third coil hereby named B_c coil. By the perturbing field or B_c field, slice positioning of the image is affected, and the slice selection fluctuates. Spatial information in the read-out and phase-encoded directions are also affected. Conducting tissues are less affected by B_c field, because of the shielding effects. Since the frequency of B_c field is independent of the given Larmor frequency,

FIG. 1. Series of image projections of water and saline solution phantom obtained with excitation power increased stepwise from the left to the right.

^{a)}Electronic mail: ueno@medes.m.u-tokyo.ac.jp

FIG. 2. Proton density reference image of the mouse head.

conductivity-enhanced images can be obtained at any frequency but in the direction perpendicular to the B_c field.

III. MATERIALS AND METHODS

Experiments were first performed on a distilled water phantom and a saline solution phantom. Both phantoms were columnar, 2 cm in diameter, and 4 cm long. A conventional spin echo (SE) sequence was used to obtain MR images. By varying the excitation rf power level stepwise, image projections in the read-out direction were obtained. A 7.05 T, 18.3 cm machine was used. The proton Larmor frequency of magnetic resonance at 7.05 T is 300 MHz. To eliminate the longitudinal T_1 relaxation effects, the repetition time T_r was set as $T_r = 10$ s. Next, a series of image projections of the head of a four-week old mouse were obtained. The SE images of the head were obtained by applying excitation pulses which were 160° , 180° , and 200° selective to the cerebrospinal fluid (CSF) of the head.

A four-turn solenoidal coil of 6 cm in diameter was fabricated as the B_c coil to produce a low-frequency sinusoidal magnetic field of 10 mT in amplitude. The amplitude of the field was comparable to the amplitudes of the reading-out gradient field and the maximum phase-encoding field. An eight-week old rat was subjected to SE imaging with a constant B_c field of sinusoidal 1 kHz.

IV. RESULTS AND DISCUSSION

Figure 1 shows a series of image projections obtained with the excitation power increased stepwise from the left to the right. The larger projections, to the right of each image, are the water phantoms, and to the left are, smaller projections of the saline solution phantom. The saline solution

FIG. 3. Series of image projections of the mouse head obtained with the excitation power increased stepwise from the left to the right.

phantom contained air as a marker. The maximum projection intensity resulted from a 90° , 270° , or 450° excitation, and the minimum projection intensity resulted from a 180° , 360° , or 540° excitation. It should be noted that the saline solution phantom requires more power for excitation than does the water phantom.

Figure 2 is a sagittal SE reference image of the mouse head obtained with 90° excitation pulses, a repetition time T_r ,

(a)

(b)

FIG. 5. Images of the rat head. (a) Flash reference image of the rat head. (b) Reference image subtracted by a B_c -applied image.

of 3000 ms, and an echo time T_e of 10 ms. The horizontal ($F1$) axis denotes the phase-encoded direction and the vertical ($F2$) axis denotes the read-out direction. Figure 3 shows a series of image projections of the same mouse head obtained in the read-out ($F2$) direction with the excitation power increased stepwise from the left to the right. The flip angle degrees 160°, 180°, and 200° were selective to the CSF of the head. The three images of Fig. 4 are head images with excitation flip angles of (a) 160°, (b) 180°, and (c) 200°. Also, the flip angles were selective to the brain CSF and all angles corresponded to the image projections (Fig. 3). All

scan parameters were identical to those of the reference image (Fig. 2) but different in flip angles. The 180° image [Fig. 4(b)] shows a slight signal from the brain and muscle tissues because there were almost no transversal components of magnetization. On the other hand, in the same 180° image, the resistive fatty tissues, which were transparent to the rf field, yielded a specific signal. By applying 180° pulses to the conducting CSF and muscle tissues, resistive fatty tissues simultaneously received excitation of the flip angles larger than 180° and produced an image signal.

Figure 5(a) is a sagittal, flash (fast low angle shot) reference image of the rat head, and Fig. 5(b) is the reference image subtracted by a continuous B_c -applied image. The signals of Fig. 5(b) are mainly from the spinal discs, ligaments, and fatty tissues. Using a continuous B_c field, more spins were perturbed in resistive tissues than in conducting tissues, and the image signal from resistive tissues fluctuated and disappeared. The possible blurring effects of B_c field in the read-out direction and phase-encoded direction can be eliminated by triggering the B_c field.

There are prior studies on B_1 field mapping³⁻⁵ but, those studies have not specifically targeted impedance distribution based on MRI techniques without electrodes. Both the large flip angle method and B_c field method are sensitive to rf inhomogeneity. In addition, both the Larmor frequency B_1 field and the low frequency B_c field are easily transmitted, absorbed, and reflected by biological tissue boundaries in varying degrees. The variance depends on the geometry of the subject, tissue properties, frequency, and the direction of B_1 or B_c field. However, in spite of these difficulties, the methods of this study are useful to obtain tomographic images of electrical impedance distributions of living organisms.

V. CONCLUSIONS

By applying large flip angles, conductivity-enhanced MR images were obtained at the Larmor frequency. By applying an additional time-varying magnetic B_c field parallel to the main static field B_0 , conductivity-enhanced images were obtained at an arbitrary frequency. The development of these methods is currently at a qualitative stage, but these are noninvasive methods used for visualization of electrical conductivity distribution *in vivo*.

Polymerization and dissolution of fibrin under homogeneous magnetic fields

M. Iwasaka, M. Takeuchi, S. Ueno, and H. Tsuda^{a)}

Department of Biomedical Engineering, Graduate School of Medicine, University of Tokyo, Tokyo 113, Japan

We investigated whether or not a mutually compensating state of coagulation and fibrinolysis is changed by homogeneous magnetic fields. We used a superconducting magnet which produced magnetic fields of up to 14 T at its center. Fibrin polymerization over time, and the subsequent dissolution of the fibrin fiber network, were observed by measuring the optical absorbance of the mixture at 350 nm. A spectrophotometer with an external optical cell box in a superconducting magnet was used. We observed that the optical absorbance of the mixture at 350 nm increased during the fibrin-polymerization process, and decreased during the fibrinolytic processes. The optical absorbance was stable in the transient state between fibrin-polymerization and fibrinolytic processes. A magnetic field of 14 T increased the rate of the polymerization process by 55%–70% compared to the control group. On the other hand, the rate of the fibrinolytic process under a magnetic field at 14 T, increased by 27%–140% compared to the control. The results indicate that the magnetic orientation of fibrin fibers accelerated both the polymerization and the dissolution of fibrin fibers. © 1998 American Institute of Physics. I. INTRODUCTION

In the final process of blood coagulation, fibrinogen molecules change to fibrin monomers through the action of protease thrombin. Fibrin monomers are polymerized and form various sizes of fibers to become a gel. The fibrinogen molecule is composed of diamagnetic material which has diamagnetic anisotropy. In the course of polymerization, the fibrin fibers orient parallel to the magnetic fields.^{1–3} Past studies have focused on the mechanisms of the polymerization process using the magnetic orientation of fibrin. To investigate the fibrin structure and the mechanism of fibrin assembly, effects of coagulation factors such as Ca^{2+} , factor XIIIa, and fibrinopeptides on magnetic orientation of fibrin were clarified.^{4–6} We reported the clotting ability of various sizes of fibrinogen fractions using a magnetic orientation technique.⁷

In this study, we carried out an experiment to investigate whether or not a mutually compensating state of coagulation and fibrinolysis is changed by static magnetic fields. We measured the sophisticated process of enzymatic reactions of thrombin and plasmin under a 14 T homogeneous magnetic field. When blood coagulation occurs, the enzyme plasmin dissolves fibrin fibers, and the blood vessel remains in a normal state. The effects of magnetic fields on enzymatic reactions, which involve enzymes such as thrombin and plasmin, are interesting because each of these enzymes has opposing roles in the process of fibrin clot formation.

II. METHODS

We used a horizontal superconducting magnet which produced magnetic fields of up to 14 T at its center. First, 3

ml of fibrinogen solution (2.4–10.7 mg/ml) was incubated for 2 min at 37 °C. Next, plasmin and thrombin were added into the fibrinogen solution, and the mixture was incubated in an optical cell both with and without a constant magnetic field at 14 T.

Fibrin polymerization over time and the resulting dissolution of the fibrin fiber network were observed by measuring the optical absorbance of the mixture at 350 nm. A polymerized fibrin fiber has an optical turbidity. The period to reach a maximum level of absorbance at 350 nm is a conventional parameter for the evaluation of fibrin formation. In the present study, we evaluated the absorbance rate at 350 nm.

We used a spectrophotometer (JASCO, model V570) which has an external optical cell box in a superconducting magnet. Two optical fibers connected the external optical cell with the spectrophotometer, as shown in Fig. 1.

III. RESULTS AND DISCUSSION

The optical absorbance of fibrin gel at 350 nm shows the level of polymerization of fibrin fibers. Thick and large fibrin fibers have large optical absorbance at 350 nm.

FIG. 1. Experimental setup for real-time measurement of the processes of fibrin formation and dissolution under strong magnetic fields.

^{a)}Clinical Laboratory, Kyushu University Hospital, Kyushu University, Fukuoka 812, Japan.

FIG. 2. Time course of the optical absorbance of the mixture at 350 nm during a fibrin polymerization process. The concentrations of fibrinogen, plasmin, and thrombin were 10.8 mg/ml, 0.28 units/ml, and 0.13 NIH units/ml, respectively.

The optical absorbance of the mixture at 350 nm increased during fibrin polymerization and decreased during the fibrinolysis, as shown in Fig. 2. The concentrations of fibrinogen, plasmin, and thrombin were 10.8 mg/ml, 0.28 units/ml, and 0.13 NIH units/ml, respectively. The optical absorbance was stable during the transient state between fibrin polymerization and the fibrinolytic processes. The experiments were carried out four times, and each time similar results were obtained.

We analyzed the time course of the optical absorbance of the mixture at 350 nm, and obtained absorbance rates for both fibrin polymerization and fibrinolysis, as shown in Fig. 3. The absorbance rates in both polymerization and fibrinolysis were calculated using a kinetics program of the spectrophotometer system. The concentration of fibrinogen was 10.8 mg/ml. The bar in positive area shows the rate of polymerization, and the bar in negative area shows the rate of fibrinolysis. A magnetic field at 14 T increased the rate in the polymerization process by 70% compared to the control group. In contrast, the rate in the fibrinolytic process under a magnetic field at 14 T decreased by 7% compared to the control. Also, a magnetic field at 14 T prolonged the duration of the transient state between fibrin polymerization and fibrinolytic processes.

FIG. 3. Absorbance rate at 350 nm under both fibrin polymerization and fibrinolytic process. The concentrations of fibrinogen, plasmin, and thrombin were 10.8 mg/ml, 0.28 units/ml, and 0.13 NIH units/ml, respectively.

FIG. 4. Absorbance rate at 350 nm under both fibrin polymerization and fibrinolytic process. The concentrations of fibrinogen, plasmin, and thrombin were 6.4 mg/ml, 0.28 units/ml, and 0.13 NIH units/ml, respectively.

Figure 4 shows the results with a fibrinogen concentration of 6.4 mg/ml. The rate of fibrin polymerization also increased under a 14 T magnetic field. The maximum levels of the absorbance and the rate of fibrinolysis, increased under a 14 T magnetic field.

Figure 5 shows the results with a fibrinogen concentration of 2.4 mg/ml. The effects of the applied magnetic field were similar to the results shown in Fig. 4.

We also obtained the enhancement of both polymerization and dissolution processes of fibrin with a low concentration of enzymes, as shown in Fig. 6.

In the case of high fibrinogen concentration, 50 mg/ml, magnetic field effects were not significant in fibrin polymerization, as shown in Fig. 7. Fibrinolysis of the polymerized fibrin did not occur due to the high density of fibrin fibers.

The results of our study indicate that the magnetic orientation of fibrin fibers accelerated the polymerization of fibrin fibers.

The complete orientation of fibrin is obtained when the magnetic energy of fibrin fibers exceeds thermal energy kT ,

$$-\frac{\Delta\chi N}{2\mu_0} B^2 > kT, \quad (1)$$

where $\Delta\chi$ is the diamagnetic anisotropy of a fibrin monomer, and N is the number of fibrin monomers in a fibrin fiber.

FIG. 5. Absorbance rate at 350 nm under both fibrin polymerization and fibrinolytic process. The concentrations of fibrinogen, plasmin, and thrombin were 2.4 mg/ml, 0.28 units/ml, and 0.13 NIH units/ml, respectively.

FIG. 6. Absorbance rate at 350 nm under both fibrin polymerization and fibrinolytic process. The concentrations of fibrinogen, plasmin, and thrombin were 3.2 mg/ml, 0.06 units/ml, and 0.03 NIH units/ml, respectively.

A fibrin fiber with more than 10^7 fibrin monomers has enough energy for complete magnetic orientation under an 8 T magnetic field at 298 K. Fibrin fibers orient parallel to the field direction.

We proposed a model for the magnetic field effect on fibrin polymerization enhancement which is shown in Fig. 8. Figure 8(a) shows the formation of fibrin fibers, so-called "protofibrils," in the early stages. Later, smaller fibrin polymers with 10^5 – 10^7 fibrin monomers aligned along the magnetic field direction. Thus, fibrins under magnetic fields form a thick and dense mass and show a high rate of optical turbidity increase.

In a previous study, we carried out an experiment to understand how the fibrin, oriented in a magnetic field, dissolves.³ Fibrin gels formed in a magnetic field were more soluble than those formed without a magnetic field. It was observed that the shapes of holes in dissolved fibrin changed to ellipsoidal patterns when fibrin plates were formed in a magnetic field at 8 T. The transverse axis of the ellipse was parallel to the magnetic fields.

FIG. 7. Absorbance rate at 350 nm under both fibrin polymerization and fibrinolytic process. The concentrations of fibrinogen, plasmin, and thrombin were 50 mg/ml, 0.81 units/ml, and 0.78 NIH units/ml, respectively.

FIG. 8. A model for the magnetic field effect on fibrin polymerization enhancement.

The present results of optical turbidity measurement also show that the oriented fibrin fibers dissolve at a high rate. It is possible that the magnetic orientation of the fibrin fibers enhanced the dissolution of fibrin by plasmin for low fibrinogen concentration. However, for high fibrinogen concentration, it was suggested that plasmin embedded in oriented fibrin gel lost its ability to dissolve the fibrin fibers.

Bioluminescence under static magnetic fields

M. Iwasaka^{a)} and S. Ueno

Department of Biomedical Engineering, Graduate School of Medicine, University of Tokyo,
Tokyo 113, Japan

In the present study, the effect of magnetic fields on the emission of light by a living system was studied. The fireflies *Hotaria parvula* and *Luciola cruciata* were used as the bioluminescence systems. The firefly light organ was fixed at the edge of an optical fiber. The emitted light was introduced into a single-channel photon-counting system using an optical fiber. We measured both the spectrum of a constant light emission and, the time course of bioluminescence pulses. Two horizontal-type superconducting magnets, which produced 8 and 14 T magnetic fields at their center, were used as the magnetic-field generators. We also carried out an *in vitro* study of bioluminescence. The enzymatic activity of luciferase was measured under a 14 T magnetic field. We measured emission spectra of bioluminescence over the interval 500–600 nm at 25 °C in a stable emission state. It was observed that the peak wavelength around 550 nm shifted to 560 nm under a 14 T magnetic field. However, the effects of magnetic fields were not significant. Also, we measured the time course of emissions at 550 nm in a transient emission state. The rate in the light intensity under a 14 T magnetic field increased compared to the control. There is a possibility that the change in the emission intensities under a magnetic field is related to a change in the biochemical systems of the firefly, such as the enzymatic process of luciferase and the excited singlet state with subsequent light emission. © 1998 American Institute of Physics.

[S0021-8979(98)38911-2]

I. INTRODUCTION

The question of whether magnetic fields affect enzymatic activities or not is of considerable interest in biochemistry and in biomagnetics. Possible biomagnetic and chemical effects can be expected when biological systems are exposed to both static magnetic fields and other energy such as light and radiation.¹ Photochemical reactions produced by a radical-pair intermediate in solution, can be exposed to show magnetic-field effects that arise from an electron-Zeeman interaction, an electron-nuclear hyperfine interaction, or a hyperfine interaction mechanism including an electron-exchange interaction in a radical-pair intermediate. A common mechanism of magnetic-field effects on photochemical processes is that a chemical yield of the cage or escape product shows a magnetic-field dependence when a single-triplet intersystem crossing is subject to magnetic perturbations. The magnetic-field effects on photochemical reactions were verified in previous studies.²

To clarify the effect of magnetic fields on enzymatic reactions in living systems, it is important to study the enzymatic reactions that involve radicals generated from nonphotochemical processes. Haberditzl reported that magnetic fields of up to 6 T enhanced the activity of catalase 4.9%–52%.³ We examined the possible effects of static magnetic fields on biochemical reactions catalyzed by xanthine oxidase and by catalase.^{1,4} It was reported that magnetic fields of 0.10–0.15 T affected B₁₂ ethanolamine ammonia lyase.⁵ While several enzymatic processes have radical pairs, it is not easy to examine the products of a radical reaction *in vivo*. However, if the products could be measured by light

emission, the real-time measurement of the radical reaction could be available in an *in vivo* system. The use of bioluminescence to investigate the interaction of magnetic fields with *in vivo* biochemical processes involving the radical pairs is effective. In the present study, the effect of magnetic fields on the emission of light by a living system was studied.

II. METHODS

A. Magnetic-field exposure systems

We used two horizontal types of superconducting magnets. The magnet 700 mm long with a bore of 100 mm in

FIG. 1. Experimental setup for the bioluminescence of a firefly.

^{a)}Electronic mail: iwasaka@medes.m.u-tokyo.ac.jp

FIG. 2. Emission spectra of firefly *Hotaria parvula* over the intervals 500–600 nm at 25 °C with and without magnetic field at 14 T.

diameter produced 8 T at its center. The magnet 480 mm long with a bore of 50 mm in diameter produced 14 T at its center. All experiments were carried out under homogeneous magnetic fields of 8 and 14 T.

B. In vivo experiments

The fireflies *Hotaria parvula* and *Luciola cruciata* were used as the bioluminescence systems. The firefly light organ was fixed at the edge of an optical fiber. The emitted light was introduced into a single-channel photon-counting system using an optical fiber, as shown in Fig. 1. We measured both the spectrum of a constant light emission and the time course of bioluminescence pulses.

C. In vitro experiments

We carried out an *in vitro* study of bioluminescence by means of a luciferin–luciferase reaction. The enzymatic activity of luciferase was measured under a 14 T magnetic field. We prepared a reaction mixture, which contained 0.1 mM of d-luciferin (RD systems Co.), 1.5–4.0 m units/ml of luciferase, 5 mM of magnesium sulfate, and 20 mM of HEPES (pH 7.7). The luciferase was a recombinant of *Luciola cruciata*.

The reaction was started by the addition of 50 μ l of ATP solution. The final concentration of ATP was changed in the range of 0.2 μ g/ml–0.2 mg/ml. Reaction mixtures were exposed to a magnetic field of 14 T for 2000 s at 25 \pm 0.1 °C. The emission of bioluminescence was stable at low intensity emissions where the optical intensity decreased below 1000 counts per second (cps). However, the emission was unstable

FIG. 3. The effects of a 14 T magnetic field on the peak wavelength at 550 nm.

FIG. 4. The effects of a 14 T magnetic field on the time course of the transient emission of the firefly *Hotaria parvula* at 550 nm.

when the optical intensities were \sim 10 kilocounts per second (kcps). We measured the spectra of bioluminescence under stable emission conditions.

III. RESULTS AND DISCUSSION

We measured the emission spectra of *in vivo* experiments of the bioluminescence of the firefly *Luciola cruciata* in an 8 T magnetic field. In the range of 25–37 °C, the peak intensity and wavelength at 435 nm changed significantly. However, the two peak wavelengths, at 435 and 550 nm, did not change in an 8 T magnetic field. The effects of an 8 T magnetic field on the emission spectrum are negligible compared to the effects of temperature.

We measured the low-intensity (<1 kcps) emission spectra of bioluminescence of *Hotaria parvula* over the interval 500–600 nm at 25 °C under a 14 T magnetic field. It was observed that the peak wavelength around 550 nm shifted to 560 nm under a 14 T magnetic field, as shown in Fig. 2. Figure 3 shows the effects of a 14 T magnetic field on the peak wavelength at 550 nm. The effects of magnetic fields were not significant.

The emission spectra of the *in vitro* luciferin–luciferase reactions were also measured under the stable states. In our experiment, the light intensities were stable at approximately

FIG. 5. Time course of the emitted light of the luciferin–luciferase *in vitro* reaction at 550 nm under a 14 T magnetic field.

FIG. 6. Rate in the emitted light intensity of the luciferin reaction at 550 nm under a 14 T magnetic field after the addition of an ATP solution.

2000 s after the addition of an ATP. A distinct effect of the magnetic field on the peak wavelength at 550 nm was not observed.

Furthermore, we measured the time course of the emission of firefly *Hotaria parvula* in a transient emission state. Figure 4 shows a time course of high-intensity (5–10 kcps) emissions at 550 nm. During the experiment, the light intensity gradually decreased; the firefly was exposed to a 14 T magnetic field, three times. It was observed that a 14 T magnetic field enhanced the inclination of emission intensity.

Figure 5 shows the time course of the emitted light of the luciferin–luciferase *in vitro* reaction at 550 nm under a 14 T magnetic field. After the addition of an ATP solution, the light intensity rapidly increased. The reaction mixture in an optical cell was inserted into the superconducting mag-

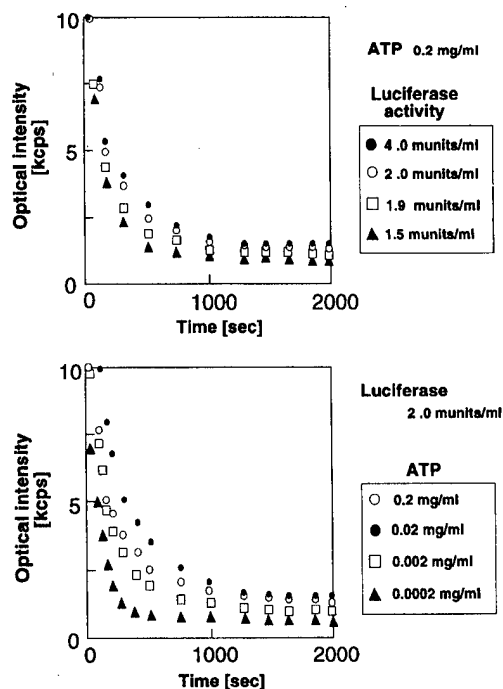

FIG. 7. Effects of the concentrations of ATP and luciferase on the time course of bioluminescence at 550 nm.

FIG. 8. The mechanism of the luciferin–luciferase reaction.

net's bore, and the decreasing light intensity was observed. The light intensity under a 14 T magnetic field decreased rapidly compared to the control. Figure 6 shows the rate of emitted light intensities at 14 T. A 14 T magnetic field affected the transient state of the time course of the light intensity.

In order to investigate the mechanism of the observed effects, we measured the time course of the emitted light, by changing the concentration of ATP and luciferase, as shown in Fig. 7. The upper figure of Fig. 7 shows results with a constant concentration of ATP and four types of luciferase activities. When the activity of luciferase decreased, optical intensities also decreased. Similarly, lowering the ATP concentration for a constant concentration of luciferase reduced the optical intensity. Decreasing the luciferase activity, the ATP concentration and a 14 T magnetic field exposure have the same effect, an optical intensity drop.

There is a possibility that the change in the emission intensities under a magnetic field is related to the change in the biochemical systems of the firefly, such as the enzymatic process of luciferase and the excited singlet state with subsequent light emission. Figure 8 shows the mechanism of the luciferin–luciferase reaction.⁶ The luciferin and luciferase form an enzyme–substrate complex, and an intermediate dioxetane produces a radical pair in the singlet state, oxyln. The excited singlet state of oxyln generates a cage product and yellow-green light. On the other hand, the triplet state generates only an escape product. It is possible that the magnetic fields affect the single–triplet intersystem crossing by electron–Zeeman interactions, i.e., Δg mechanism.²

IV. CONCLUSION

In conclusion, it was found that the bioluminescence of the luciferin–luciferase reaction was changed under a magnetic field at 14 T. The static magnetic fields of 14 T enhanced the decrease of emission intensity. The static magnetic fields of 8–14 T had no distinct effects on the peak wavelength at 400–600 nm.

Structure of water molecules under 14 T magnetic field

M. Iwasaka^{a)} and S. Ueno

Department of Biomedical Engineering, Graduate School of Medicine, University of Tokyo,
Tokyo 113, Japan

In this study, we investigated the effects of strong magnetic fields of up to 14 T on the near-infrared spectrum of water molecules. We used a near-infrared spectrophotometer, which has an external optical cell box in a 14 T superconducting magnet. We measured the near-infrared spectrum of water in the range of 900–2000 nm by changing the optical path lengths from 0.1 to 100 mm. The peak wavelengths in the near-infrared spectrum in the range of 900–2000 nm of water, increased in length by 1–3 nm under a 14 T magnetic field. Also, we measured a near-infrared spectrum of glucose solutions under a magnetic field at 14 T to investigate the hydration of sugar. In contrast to the case of water, the peak wavelength of glucose solutions showed blueshift under a 14 T magnetic field. When the magnetic fields were changed from 0 to 14 T, the differential optical absorbance of the glucose solution at 958 nm increased compared to the controls. There is a possibility that the 14 T magnetic field affects the formation of hydrogen bonds of water molecules and the hydration of glucose molecules. © 1998 American Institute of Physics. I. INTRODUCTION

Water, an important material for living systems, is a diamagnetic material. We have observed the phenomenon that the surface of water was parted by magnetic fields and the bottom of the water chamber appeared when water was exposed to magnetic fields up to 8 T.^{1,2} It is important to know whether or not magnetic fields affect the property of water molecules. As water is an essential material in the living body, the understanding of the behavior of water under magnetic fields provides information to discuss the effects of magnetic fields on living systems.

The so called ‘Moses’ effect’ can be explained by the diamagnetic property of water. Since water is diamagnetic, when a magnetic force acting on water reaches a high enough value, it presses back the water. Also, it is important to understand the mechanism of the interaction of magnetic fields with organic and water molecules. A diamagnetic macromolecule such as fibrin is a good model for studying biomagnetic effects because fibrin polymers are oriented parallel to the direction of magnetic fields.³ Compared to paramagnetic inorganic materials, solutions of biological materials such as proteins and amino acids are mostly diamagnetic, and their magnetic susceptibility is small.

We reported the effect of magnetic fields up to 8 T on the enzymatic reaction of glucose oxidase with *D*-glucose using an electrochemical technique.⁴ We observed that electric currents decreased by 10%–20% after a magnetic-field exposure for 1–2 h. We conjecture that the diffusion process of glucose in aqueous solution, into the pore of the electrode, appeared to be inhibited by the magnetic field. Also, it is important to investigate the effects of dissolved oxygen concentration on the properties of aqueous solution.^{5,6} The reported effect of a magnetic field on the diffusion of saccharides through a porous membrane was obtained at 1.1 T.⁷ It

is possible for a strong magnetic field to affect the hydration of sugar.

In this study, we investigated the effects of strong magnetic fields of up to 14 T on the near-infrared spectrum of water and a sugar solution.

II. METHODS

We investigated the near-infrared spectrum of aqueous solutions using a horizontal type of superconducting magnet, which produces 14 T at its center. We used a near-infrared spectrophotometer, which has an external optical cell box in a superconducting magnet, as shown in Fig. 1. Two optical fibers connected the external optical cell with the spectrophotometer.

We measured the near-infrared spectrum of aqueous solutions in the range of 900–2000 nm. Each of the spectra was obtained from 100 to 600 measurements. The optical

FIG. 1. Experimental setup for near-infrared absorbance measurement of water and glucose solutions under magnetic fields of up to 14 T.

^{a)}Electronic mail: iwasaka@medes.m.u-tokyo.ac.jp

FIG. 2. Effects of a 14 T magnetic field on near-infrared spectrum of water at 900–1000 nm. Optical length is 30 mm.

path lengths of the cells were 0.1, 10, 30, and 100 mm. All measurements were carried out in a temperature-stabilized holder at 25 °C.

Also, we measured the near-infrared absorbance of a sugar solution under a magnetic field at 14 T to investigate the hydration of the solute in aqueous solution. The hydration of *D*-glucose was investigated by the absorbance of solutes at 958 nm.⁸ We measured the absorbance of 2.3, 1, and 0.1 M of *D*-glucose solution and water.

III. RESULTS AND DISCUSSION

Figure 2 shows the effect of a 14 T magnetic field on the near-infrared spectrum of water at 900–1000 nm. The optical path length of the cell was 30 mm. A peak wavelength at 970 nm shifted to a longer wavelength in a 14 T magnetic field. Each of the spectra was the average of 600 measurements.

We measured spectra of two types of glucose solution, 2.3 and 1.0 M, in the 30 mm optical path. Each of the spectra was obtained from 600 measurements. Figure 3(a) shows the spectrum of 2.3 M of the *D*-glucose solution. The peak wavelength of 2.3 M glucose shifted to a longer wavelength compared to the water without magnetic-field exposures. In contrast to the case of water, the peak wavelength of 2.3 M glucose showed blueshift under a 14 T magnetic field. The effect of magnetic fields on 1.0 M of the *D*-glucose solution was the blueshift of a peak wavelength, as shown in Fig. 3(b).

Figure 4 shows the effects of magnetic fields of up to 14 T on the near-infrared absorbance of *D*-glucose solutions and water at 958 nm. Figures 4(a) and 4(b) show the results in the optical paths of 10 and 100 mm, respectively.

The optical absorbance at 958 nm in the 10 mm optical path was adjusted to zero when an empty cell was put in the optical cell holder. When the magnetic fields were changed from 0 to 14 T, the absorbance of 1 M of the *D*-glucose solution increased by 0.006 [optical density (OD)], as shown in Fig. 4(a). The absorbance at 958 nm of 1 M of the *D*-glucose solution was stable in the range of 0–14 T. How-

(a) 2.3M of *D*-glucose solution

(b) 1.0M of *D*-glucose solution

FIG. 3. Effects of a 14 T magnetic field on near-infrared spectra of *D*-glucose solutions at 900–1000 nm. (a) 1.0 M of *D*-glucose solution, and (b) 2.3 M of *D*-glucose solution. Optical length is 30 mm.

ever, when we measured the absorbance at 958 nm of distilled water under magnetic fields, the absorbance decreased by 0.010 (OD).

In the experiments with the 100 mm optical path cell, the absorbance level was adjusted to zero by water. As shown in Fig. 4(b), when the magnetic fields were changed from 0 to 14 T, the absorbance of 1 M of the *D*-glucose solution increased by 0.2 (OD). When we measured the absorbance of distilled water at 958 nm under magnetic fields, distinct changes in the absorbance were not observed.

The results of Figs. 3 and 4 indicate that the increase in the optical absorbance at 958 nm under magnetic fields was because a property of the glucose solution, such as the hydration of glucose, changed under magnetic fields of up to 14 T.

We investigated the property of near-infrared absorbance of water by changing the optical path length for a second time. Figure 5 shows the time course of the change in the peak wavelength of water at 977 nm. The optical path length was 10 mm. Each of the spectra was obtained from 100 measurements. Before magnetic-field exposure, the peak wavelength was 977.0–977.1 nm. The peak shifted to 978.0 nm under a 14 T magnetic field, and gradually shifted to the

(a) Optical path length = 10mm

(b) Optical path length = 100mm

FIG. 4. Near-infrared absorbance of *D*-glucose solutions and water at 958 nm under magnetic fields of up to 14 T.

shorter wavelength after the magnetic field was turned off.

Figure 6 shows the effects of a 14 T magnetic field on the peak wavelength of water at 1920–1940 nm. The optical length was 0.1 mm. Each of the spectra was obtained from 900 measurements. The peak wavelength of water shifted from 1927.2 ± 0.9 nm to 1929.4 ± 0.8 nm under the 14 T magnetic field.

An enhancement of the formation of hydrogen bonds in water molecules under high pressure was reported.⁹ The bottom figures of Fig. 6 show an enhancement of the formation of hydrogen bonds in water molecules. The near-infrared

FIG. 5. Effects of a 14 T magnetic field on the peak wavelength of water at 978–980 nm. Optical length is 10 mm.

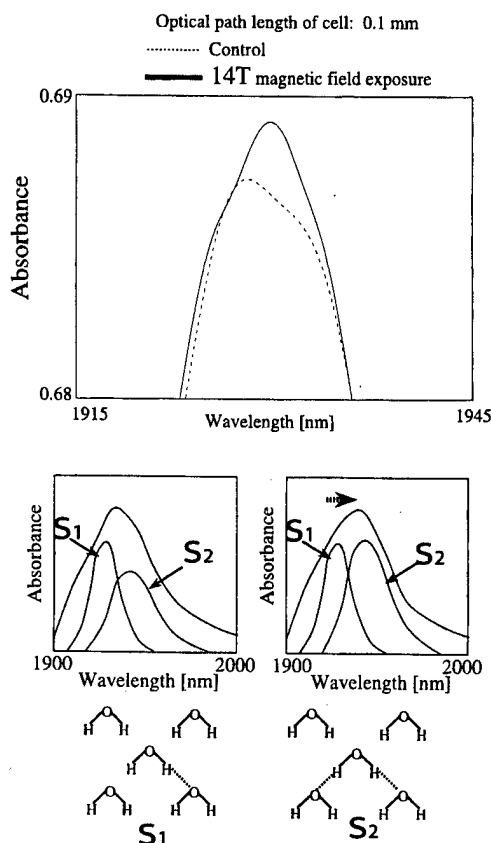

FIG. 6. Effects of a 14 T magnetic field on the peak wavelength of water at 1920–1940 nm. Optical length is 0.1 mm. The lower figure shows an enhancement of the formation of hydrogen bonds in water molecules (Ref. 9). The species of water molecules, which have two hydrogen bonds, increased in number, and the peak wavelength shifts to longer wavelengths.

spectrum of water around 1900 nm originates from the species of water molecules S1 and S2.⁹ The species of water molecules, (S2) which have two hydrogen bonds, increased in number, and the peak wavelength shifts to longer wavelengths. There is a possibility that the species of water molecules, which have two hydrogen bonds between water molecules, increased in number under the 14 T magnetic field. Also, we need to investigate the effects of dissolved oxygen on the optical properties of aqueous solutions.^{5,6}

Estimation of multiple sources using a three-dimensional vector measurement of a magnetoencephalogram

Koichiro Kobayashi^{a)} and Yoshinori Uchikawa

Tokyo Denki University, Ishizaka Hatoyama Hiki-gun, Saitama, 350-0394 Japan

We developed a three-dimensional (3D) second-order gradiometer connected to three superconducting quantum interference devices (SQUIDs) for vector measurement of a magnetoencephalogram (MEG) that can detect magnetic-field components perpendicular and tangential to the scalp simultaneously. Each coil is orthogonally wound with Nb-Ti wire on a rectangular solid $3 \times 3 \times 6$ cm. To assess discrimination and separation of multiple sources, we carried out a 3D vector measurement of the MEG with a mixed auditory evoked field (AEF) and a somatosensory evoked field (SEF) overlapping in time. The magnetic-field distribution perpendicular to the scalp was not helpful in estimating the location and number of sources, owing to the lack of a dipole pattern. But the magnetic-field distribution tangential to the scalp can provide information about constraint conditions by visual inspection. We estimated multiple sources of the mixed AEF and SEF from the MEG data of the magnetic field tangential to the scalp and confirmed by comparison with magnetic resonance imaging (MRI) of a subject's head superimposed source locations. We conclude that this 3D second-order gradiometer can provide constraint conditions by visual inspection for calculating the inverse problem with multiple sources. © 1998 American Institute of Physics. [S0021-8979(98)39111-2]

INTRODUCTION

Magnetoencephalogram (MEG) measurement of the magnetic field perpendicular to the scalp is widely used. There are problems of separating multiple sources overlapping in time when many distinct areas of the cortex are active.¹⁻⁴ We developed a three-dimensional (3D) second-order gradiometer connected to three superconducting quantum interference devices (SQUIDs) for vector measurement of the MEG that can detect magnetic-field components perpendicular (Br) and tangential ($B\theta, B\phi$) to the scalp simultaneously.⁵ The magnetic-field distribution tangential to the scalp can provide information about constraint conditions by visual inspection. This paper presents a 3D vector measurement of the MEG with a mixed auditory evoked field (AEF) and a somatosensory evoked field (SEF) overlapping in time, and also presents an estimation of multiple sources using the MEG data of the magnetic-field components perpendicular and tangential to the scalp.

METHOD

A 3D vector measurement of the MEG was carried out using a 3D second-order gradiometer shown in Fig. 1(a). The coordinate system is shown in Fig. 1(b). The 3D second-order gradiometer is orthogonally wound with Nb-Ti wire on a rectangular solid $3 \times 3 \times 6$ cm. The magnetic-field output of this gradiometer is expressed as follows:

$$Br = B(r, \theta, \phi) - 2B(r + \Delta r, \theta, \phi) + B(r + 2\Delta r, \theta, \phi), \quad (1)$$

$$B\theta = B(r, \theta, \phi) - 2B(r, \theta + \Delta \theta, \phi) + B(r, \theta + 2\Delta \theta, \phi), \quad (2)$$

$$B\phi = B(r, \theta, \phi) - 2B(r, \theta, \phi + \Delta \phi) + B(r, \theta, \phi + 2\Delta \phi), \quad (3)$$

where (r, θ, ϕ) indicates the lowest place of the Br component coil shown in Fig. 1(a). Δr is a base line (2.8 cm) of a Br coil. $\Delta \theta$ and $\Delta \phi$ indicate a base line (1.4 cm) of a coil for $B\theta$ and $B\phi$.

A multiple source estimation study was done using the moving dipole inverse solution with a spherical homogeneous conductor model (85 mm radius) as a human head. Multiple sources are estimated by minimizing the cost function, which is the least-squares fit between the measured magnetic field and calculated magnetic field. In this method, source parameters such as amplitude and orientation were varied, and the minimum cost function was obtained by iterative calculation. The cost function f is defined as

$$f = \frac{\sum_{i=1}^n (Bm_i - Be_i)^2}{\sum_{i=1}^n (Bm_i)^2}, \quad (4)$$

(a) 3-D second-order gradiometer

(b) coordinate system

FIG. 1. Configuration of a 3D second-order gradiometer and the coordinate system.

FIG. 2. Isofield contour maps consisting of the mixed AEF (120 ms) and SEF (80 ms) overlapping in time. (a), (b), and (c) measured MEG; and (d), (e), and (f) calculated MEG.

where Bm_i is the measured magnetic field at i th position, and Be_i is the calculated field. The goodness-of-fit G is defined as

$$G = \sqrt{1 - f} \times 100 \quad (\%). \quad (5)$$

The main elements of the calculation process for the inverse solution are as follows. The initial parameters of the multiple dipoles are determined by topographical features of the tangential magnetic-field distribution ($B\theta, B\phi$). Namely, the number and the location of the dipoles are given from tangential magnetic-field extremes since the tangential magnetic field shows maximum or minimum field just above the location of a single dipole.⁵ The amplitudes of the dipoles are also given by the magnetic-field extremes. Then, a least-squares calculation [Eq. (4) of the cost function] was performed for the perpendicular magnetic field (Br) using these initial parameters of sources obtained from the tangential magnetic field ($B\theta, B\phi$). A unique characteristic of this inverse calculation is the use of the initial parameters obtained from the tangential field as the constraint conditions.

MEG MEASUREMENT AND SOURCE ESTIMATION

We carried out a 3D MEG measurement of mixed AEF and SEF overlapping in time. The AEF was elicited by 1 kHz tone bursts of 50 ms duration to the right ear. The SEF was elicited by electric pulses of 0.2 ms duration with 6–8 mA to the median nerve of the right wrist. The interval of stimulation was 500 ms. Stimulation to the median nerve was delivered 40 ms later than to the ear. There were two evoked fields, namely, the mixed AEF and SEF, overlapping in time. There were 30 measurement positions on the scalp. All magnetic data were averaged for 400 measurements at each position. The sampling interval was 0.5 ms. A band-pass filter was used in the range of 0.5–40 Hz.

Figures 2(a), 2(b), and 2(c) show an example of isofield contour maps at 120 ms latency of the AEF and at 80 ms

FIG. 3. MRI of a subject's head showing the superimposed source localization of the AEF (open square) and the SEF (open circle).

latency of the SEF. Solid lines (positive field) of the Br component shows the outflow of the magnetic flux from the scalp. These lines (positive field) of $B\theta$ and $B\phi$ show a magnetic flux directed along the latitudes and longitudes shown in Fig. 1(b). As shown in Fig. 2(a), the contour map of Br shows one extremum at measurement position D4 that is not a dipole pattern. This map was not helpful in estimating the location and the number of sources. By referring to the contour maps of $B\theta$ and $B\phi$ shown in Figs. 2(b) and 2(c), we can clearly see two extremes with opposite polarity on both contour maps. Namely, these magnetic fields consist of two sources with opposite polarity underlying each extreme.⁶ We can obtain the initial parameters of the number, the locations, and the directions of the sources by visual inspection from these contour maps. We carried out source estimation using these initial parameters. Figures 2(d), 2(e), and 2(f) show calculated isofield contour maps. The calculated maps $B\theta$ and $B\phi$ were estimated from the result of the inverse solution from Br . The goodness of fit (G) of Br is 92.4%, and the goodness of fit (G) of $B\theta$ and $B\phi$ are 88.7% and 88.6%, respectively.

Figure 3 shows the magnetic resonance imaging (MRI) of a subject's head. Estimated sources are superimposed on the MRI. The localization of the AEF source (open square) at 120 ms latency on the MRI was estimated at the gyrus of the sylvian sulcus with a depth of 1.8 cm below the scalp, which is in the auditory area. Localization of the SEF source (open circle) at 80 ms latency on the MRI was estimated at the gyrus of the central sulcus with a depth of 1.4 cm from the scalp, which is the somatosensory area. The results of this study, analyzing magnetic fields over the human primary cortices, agree in general terms with the related findings in previous human studies.^{7,8}

CONCLUSION

We developed a 3D second-order gradiometer connected to three SQUIDS for vector measurement of the MEG that can detect magnetic-field components perpendicular and tangential to the scalp simultaneously. To assess discrimination and separation of multiple sources, we carried out 3D vector measurements of the MEG with the mixed AEF and SEF overlapping in time. We estimated multiple sources from the MEG data and confirmed source locations are reasonable by comparison with the MRI of the subject's head. We conclude

that this 3D vector magnetic-field measurement can provide information on constraint conditions, which can be obtained from the tangential magnetic field when we calculate the inverse problem with multiple sources. Up to the present time, we have used only the magnetic field perpendicular to the scalp.

S. Nakayama

Seiko Instruments Inc., Matsudo, Chiba 271, Japan

We have developed a multichannel high-resolution superconducting quantum interference device magnetometer for measuring biomagnetic fields produced by small animals. We measured the magnetocardiogram produced by a rat. Topographies of the *P* wave, *QRS* wave, and *T* wave of the rat magnetocardiogram were obtained. We also measured the magnetoretinogram, visually evoked magnetic fields, and auditory evoked magnetic fields of the rat. The signals of the magnetoretinogram appeared at 60 ms latency and the field intensities were about 0.6 pT. It was not possible to obtain the clear visually evoked fields because those signals were hidden behind the magnetoretinogram. It was possible to obtain auditory evoked magnetic fields of the rat. The significant differences of the wave forms were observed in both sides of the right ear, which are separated by 15 mm. Our system has adequate spatial resolution for measurement of the magnetocardiogram and auditory evoked magnetic fields produced by small animals. © 1998 American Institute of Physics. [S0021-8979(98)39211-7]

INTRODUCTION

A dc superconducting quantum interference device (SQUID) system is desired for the study of biomagnetism. It is especially necessary for use in medical diagnosis and the study of higher brain functions. The main aim of measurement of biomagnetic fields is to estimate the sources of electrical activity in the brain. Many studies of functional organization of the human brain have been made through a technique using the magnetoencephalogram (MEG). Most of these investigations were concerned with estimation of localization in evoked magnetic fields. Sources of these evoked fields are assumed as a single current dipole. It is sufficient to assume a single current dipole as the source within the limits of sources in the primary sensory cortex of the brain. However, concerning higher brain functions such as memory, perception, and learning, a single dipole is not sufficient as the electrical activities of the brain are complex. It is important to consider spatially distributed multiple dipoles or spreading dipoles as the sources of magnetic fields. But, it is difficult to solve the inverse problem using this type of source model. Knowledge about the nature of the generator of magnetic fields is required for advancing source estimation. Besides, for the advancement of clinical applications of the MEG and magnetocardiogram (MCG), it is necessary to investigate the relationship between diseases and induced biomagnetic fields using an experimental animal model. Typical SQUID magnetometers are constructed with 15–25 mm diameter pickup coils and the distance between each coil is 30–40 mm. This type of coil configuration is designed for the human brain. Because of limited spatial resolution, this configuration cannot be used for the MEG measurements of

small animals such as the rat. A high-resolution magnetometer is needed to measure the biomagnetic fields produced by small animals in conjunction with more invasive physiologic measurements.

Buchanan *et al.*¹ and Wikswo *et al.*² developed a high-resolution SQUID magnetometer, called a micro-SQUID, which was designed for the experiments on *in vitro* preparations such as isolated nerves and muscles and slices of brain tissue. Measurement of *in vitro* preparations would benefit from 1 to 2 mm resolution. Using the micro-SQUID, magnetic evoked fields from an *in vivo* preparation were recorded by Okada *et al.*³ and Kyuhou and Okada.⁴ Experiments on small animals such as the rat or the cat would benefit from 3 to 5 mm resolution. In this study, we have designed a high-resolution SQUID magnetometer for measurement of the biomagnetic fields produced by small animals.

We measured the MCG produced by a rat. The magnetoretinogram (MRG) of the rat, which is produced by the retina in response to photic stimulation and the auditory evoked magnetic fields, were also recorded. Our system has adequate spatial resolution for the measurement of biomagnetic fields produced by small animals.

SYSTEM

The system consists of a 12-channel SQUID gradiometer installed in a five-layer magnetically shielded room. A pickup coil with a diameter of 5 mm was selected. Twelve pickup coils were located on a 7.5 mm grid. Each pickup coil consisted of a first-order gradiometer, which has a 15 mm base line as shown in Fig. 1. The distance between the pickup coil and the outside surface of the dewar was 5 mm. The field sensitivity was $100 \text{ fT}/\sqrt{\text{Hz}}$ in the frequency of the white-noise region. While the absolute sensitivity of this sys-

^{a)}Electronic mail: iramina@medes.m.u-tokyo.ac.jp

FIG. 1. Sensor layout and pick-up coil of a 12-channel high-resolution SQUID system.

tem is lower than in a conventional SQUID system, the relative sensitivity compares favorably to the conventional SQUID because of the reduced coil-to-source spacing.

MEASUREMENT OF MAGNETOCARDIOGRAM OF THE RAT

Four adult rats, ranging in weight from 0.2 to 0.3 kg, were used in the study. They were anesthetized with urethane (0.4 mg/100 g) intraperitoneally. Figure 2 shows the MCG signals and electrocardiogram (ECG) signal recorded simultaneously from a rat. The MCG signals are filtered from 0.5 to 100 Hz and averaged 100 times at the *QRS* wave of the ECG as the trigger. Significant differences are observed in the wave-form shape between the points separated by only 15 mm. We measured the MCG at 63 points over the breast of the rat and made isocountour maps at several time points as shown in Fig. 3. Each pattern shows the dipole pattern.

FIG. 2. MCGs and ECG of a rat (100 average). The MCGs were measured at 63 points on the grid as shown in the figure.

FIG. 3. Topographies of the MCGs during the (a), (b), (c), (d), and (e) periods, which are shown in the wave form of the ECG.

MEASUREMENT OF VISUALLY EVOKED MAGNETIC FIELDS

Three adult rats, ranging in weight from 0.25 to 0.3 kg, were used in the study. They were anesthetized with urethane (0.4 mg/100 g) intraperitoneally. Visual stimuli were presented unilaterally with a strobe light. Concentrated points of light were delivered to the right eye through an optical fiber. The ends of the optical fiber was placed 0.1 m from the eye. The left eye was covered by an eye mask. In order to investigate the effect of the magnetic fields produced from the retina, the electroretinogram (ERG) was measured using a contact-lens-type electrode. Figure 4 shows visually evoked

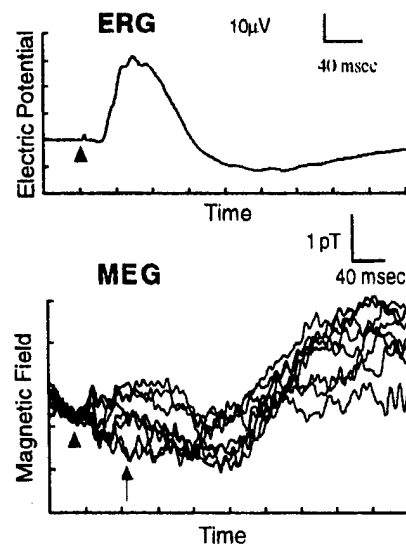

FIG. 4. Visual evoked magnetic fields of the rat. Measurement points are shown by the black dot in Fig. 5.

FIG. 5. Topography of the VEF and the estimated dipole.

fields (VEFs), which were measured at six points along a straight line over both eyes, and the ERG of the right eye of the rat. In the ERG, the negative peak appeared at 60 ms and the ERG signal changed slowly. The VEF signal had a slow component similar to the ERG signal. The VEF and MRG were superposed together because the ERG of the rat was a large signal and the eyes and the brain were close together. It is difficult to discriminate the VEF signals from the MRG signals using this SQUID magnetometer. The topography at 60 ms latency is obtained as shown in Fig. 5. From this topography one dipole, which was located at the point of right eyeball, was estimated as the source of the ERG.

MEASUREMENT OF AUDITORY EVOKED MAGNETIC FIELDS

Three adult rats, ranging in weight from 0.25 to 0.3 kg, were used in the study. They were anesthetized with urethane (0.4 mg/100 g) intraperitoneally. We used tone bursts of 3 kHz with 10 ms duration as the auditory stimuli. The stimuli were presented to the left ear of the rat through a plastic tube. Figure 6 shows the superimposed superposition of all ten wave forms of the auditory evoked magnetic fields. Magnetic signals were filtered from 1 to 100 Hz and averaged 4000 times. The small peak of the magnetic fields appeared at a

FIG. 6. The superposition of ten curves of evoked magnetic fields in the stimulation of tone bursts to the left ear of the rat.

FIG. 7. Topography of the peak at 34 ms latency and the estimated dipole.

latency about 10 ms and the large peak appeared at a latency 34 ms. Figure 7 shows the isocontour map over the head of the rat at 34 ms latency. The peak of the emerging flux is anterior to the right ear, and the peak of the entering flux is posterior to the right ear. The source of this peak is estimated at a point, which is 3 mm lateral from the meatus acusticus externus.

DISCUSSION

In this study, we were able to measure the MCG and the MEG of the rat with adequate spatial resolution. Animal experiments using a high-resolution SQUID in conjunction with more invasive physiological measurements, may contribute to the further understanding of the physiological basis of the MEG, and the advancement of solving the inverse problem. We used normal healthy rats in this study. However, in animal experiments it is possible to make abnormal rat models with diseases such as myocardial infarction or cerebral infarction. Using the abnormal rat model, we can investigate the relationships between the disease and biomagnetic fields with the possibilities of making diagnoses of abnormal activity. Hence, the MCG and MEG may become useful noninvasive diagnostic procedures for the investigation of abnormal cardiac or brain activity.

Magnetic properties and ordering in C-coated $\text{Fe}_x\text{Co}_{1-x}$ alloy nanocrystals

Z. Turgut, J. H. Scott, M. Q. Huang, S. A. Majetich, and M. E. McHenry
*Department of Materials Science and Engineering, Carnegie Mellon University, Pittsburgh,
Pennsylvania 15213*

C-coated $\text{Fe}_x\text{Co}_{1-x}$ ($x=0.50, 0.45, 0.40, 0.35, 0.30, 0.25$) nanoparticles were produced using a rf plasma torch. The only C source was acetylene used as a carrier gas. Structural determination by x-ray diffraction indicated a single disordered bcc α -FeCo phase along with graphitic C for all compositions. A Scherrer analysis of the peak widths revealed particles to have an average diameter of 50 nm. A broad log-normal size distribution was found from transmission electron microscopy observations. Magnetic hysteresis loops have been measured to temperatures exceeding 1050 K and revealed relatively high room temperature coercivities (200–400 Oe), with a strong compositional variation similar to that observed in bulk alloys. Larger coercivities are consistent with particles near the monodomain size for these alloys. The temperature dependence of the magnetization revealed the effects of atomic ordering. The variation of the saturation magnetization as a function of temperature showed a discontinuity near the bulk order–disorder ($\alpha \rightarrow \alpha'$) transformation temperature, as well as loss of magnetization at the $\alpha \rightarrow \gamma$ structural phase transition temperature. Other features of $M(T)$ near 500–550 °C are consistent with prior observations of a “550 °C structural anomaly” which has been observed in bulk alloys with less than perfect order. © 1998 American Institute of Physics. I. INTRODUCTION

The technical importance of FeCo alloys arises from their high saturation magnetization and Curie temperature which cannot be matched by any other alloy system. The high saturation magnetization of up to 2.4 and the Curie temperature about 950 °C are characteristics for the FeCo alloys with compositions 25%–50% Co. Alloys near equiatomic compositions are particularly soft and exhibit large permeabilities¹ which can be attributed to a zero crossing of the first order magnetic anisotropy constant, K_1 near this composition. We have described our initial attempts to produce FeCo[C] nanoparticles as precursors for the eventual production of a dense compacted nanocrystalline soft alloy.²

FeCo alloys in the composition range of about 30%–70% Co undergo a continuous (i.e., higher than first order) order–disorder phase transformation at a maximum temperature of 730 °C at the equiatomic composition. The change in the structure from the disordered α -bcc(A1) to the ordered α' -CsCl(B2) appears as a λ type anomaly in the heat temperature spectra. The composition dependence of this order–disorder transformation of bulk FeCo alloys is well established by specific heat measurements³ and neutron diffraction.⁴

It has been reported by many workers that in the specific heat curve of the ordered FeCo superlattice alloy, there is a peak of unknown origin at about 550 °C in addition to that for the order–disorder transformation which occurs at higher temperatures. A complete explanation of this so called 550 °C anomaly in bulk FeCo alloy which has also been observed in discontinuities in the T dependence of the electrical resistance, saturation magnetization, specific heat hardness, and thermo electromotive force has not been given yet.⁵

It has, however, been concluded that the 550 °C anomaly does not exist in equilibrium and is rather associated with metastable disordered FeCo.⁶

In previously reported work⁷ we have given magnetic evidence for the order–disorder transformation in a nanocrystalline $\text{Fe}_{50}\text{Co}_{50}$ alloy produced in carbon-arc. The compositional dependence of this structural transformation has not been studied until now in nanocrystalline alloy particles. Here we report our success to synthesis this nanocrystalline powders by a rf plasma torch route and our investigation of the compositional dependence of the ordering temperature for $\text{Fe}_x\text{Co}_{1-x}[\text{C}]$ ($x=0.55, 0.60, 0.65, 0.70$, and 0.75) nanocrystalline alloy compositions. We briefly discuss the existence of 550 °C anomaly in our nanocrystalline systems and results of measurements of the ordering transformation kinetics.

II. EXPERIMENT

We have employed a radio frequency plasma system (Fig. 1) consisting of a TEKNA PL 50 type plasma torch head and a gas expansion-reaction vessel connected to a filtering unit. A 50 kW, 3 MHz power supply (Ilepel) was used. Argon gas flowing at 40 standard liters per minute (slpm) was used as plasma gas and the sheath gas was consisted of 80 slpm Ar mixed with 9 slpm of hydrogen. A 6–10 μm Fe powder and 1.6 μm Co powder mixture was used as a starting feedstock and injected axially into the plasma stream through an injection probe with the aid of a screw driven powder feeder and 3 slpm Ar as a carrier gas. Acetylene was introduced into the carrier gas and powder mixture between powder feeder and injection probe as a carbon source for coating purposes.

FIG. 1. (a) A detailed schematic representation of plasma torch head. (b) The rf plasma torch reaction with reaction chamber and porous metal filters.

X-ray diffraction characterization of the as-synthesized nanoparticles was carried out on a Rikagu θ - θ diffractometer using Cu $K\alpha$ radiation. Transmission electron microscopy (TEM) on a JEOL 4000 EX was used to examine the coating morphology. A high temperature vibrating-sample magnetometer (with a Lake Shore Model 7300 controller) was employed for the magnetic measurements up to 1000 °C.

III. RESULTS AND DISCUSSION

We have only observed disordered bcc (α -Fe), fcc Co, and graphitic carbon by x-ray diffraction with no observation of carbides, oxides, or the hcp ϵ -Co phase. A Scherrer analysis of the peak broadening indicated an average particle diameter of $d \sim 50$ nm which is in reasonable agreement with TEM observations of particle size with a Gaussian type size distribution. High temperature magnetic measurements revealed that the bcc (α -Fe) structure is in disordered metastable state as produced.

Figure 2(a) shows saturation magnetization as a function of composition before and after annealing at 800 °C. The highest M_s value is observed at composition 70% Fe as predicted by the Slatter-Pauling curve. After annealing reordering of the initially disordered particles results in an increase of the saturation magnetization as was detected by neutron

diffraction studies. Figure 2(b) shows coercivity as a function of composition. The initial permeability measurements for bulk Fe give lower values at compositions close to the 70% Fe-30% Co which can be thought because of the higher coercivities at this composition.

Figure 3(a) illustrates the thermomagnetic data at $H = 500$ Oe for various $\text{Fe}_x\text{Co}_{1-x}[\text{C}]$ alloy nanoparticles. Heating rate was 4 °C/min for these series of experiments. It is surprising that no compositional dependence of the reordering temperature was observed. It is possible to argue that, nanocrystalline materials are composed of randomly arranged surface atoms and increased temperature leads to the relaxation of interfacial atoms which makes the surface of the particles more compact and surface atoms more ordered, so that magnetization increases. But the differential thermal analysis results in a previous work⁷ convinced us that the peak in the heating branch corresponds to the reordering phenomena. From this it may be suggested that contribution of reordering to an increase in magnetization is greater than that of surface relaxation. No compositional dependence, on the other hand, can be related to a faster kinetic nature of the nanocrystalline particles. In nanocrystalline particles an enormous enhancement of diffusivity has been reported.⁸

FIG. 2. (a) Composition dependence of saturation magnetization for as-produced disordered and annealed-ordered nanocrystals. (b) Coercivity change as a function of composition for the same nanocrystals.

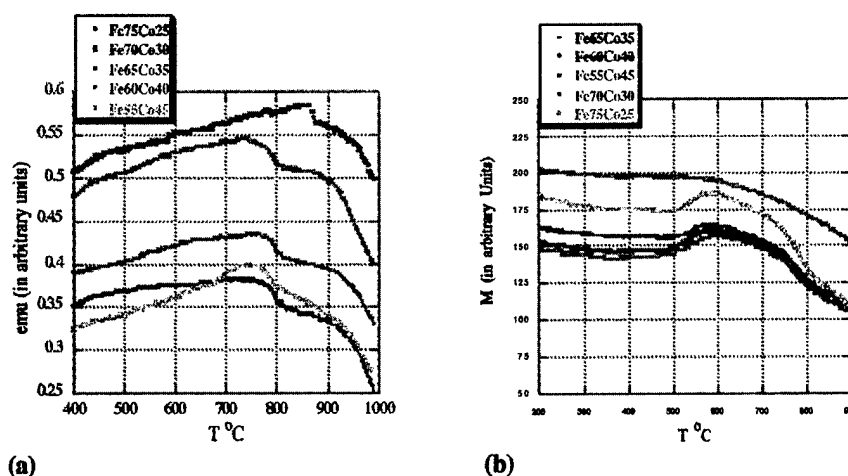

FIG. 3. (a) Magnetization vs temperature data taken at 500 Oe and 4 °C/min. heating rate for various $\text{Fe}_x\text{Co}_{1-x}[\text{C}]$ nanoparticles. (b) Same response taken at 10 kOe and 2 °C/min heating rate.

Figure 3(b) shows high field thermomagnetic data for $\text{Fe}_x\text{Co}_{1-x}[\text{C}]$ alloy nanocrystals where $H=10$ kOe with a heating rate of 2 °C/min. Again no compositional dependence of the reordering temperature was observed for the saturation magnetization. Another observation was that the presence of 550 °C anomaly which occurs as a decrease in saturation magnetization with increasing temperatures up to 510 °C. The $\text{Fe}_{70}\text{Co}_{30}$ composition leaves the characteristics of other compositions with the presence of very small anomalous effect of temperature. This result is in good agreement with Velisek,⁹ showed that based on the calorimetric studies, while $\text{Fe}_{50}\text{Co}_{50}$ composition shows 550 °C anomaly accompanied with the change of specific heat at this temperature, Fe_3Co composition shows a small degree of anomaly at this temperature. Our measurements on annealed samples showed that while the anomaly is observed in compositions (rather than $\text{Fe}_{70}\text{Co}_{30}$ composition) not depending on the initial structure is ordered or metastable disordered, initially ordered $\text{Fe}_{70}\text{Co}_{30}$ composition revealed no anomaly. In nanocrystalline materials the anomaly occurs at temperatures well below 550 °C which can be concluded from the fact of high diffusivity in this particles.

A large amount of work based on resistivity measurements concluded that the 550 °C anomaly does not exist in equilibrium. Yokoyama⁶ has reported that it takes about 15 h

for initially disordered FeCo bulk sample to reach the equilibrium at temperature 475 °C. Figure 4 shows the time response of magnetization of $\text{Fe}_{50}\text{Co}_{50}$ nanocrystalline alloy at 400 °C and 500 Oe. For a nanocrystalline material it takes about 1 h to reach the equilibrium at a given temperature even at relatively lower temperatures. As the temperature is further increased faster time response is observed, i.e., 30 min at temperature 650 °C. Having this high diffusivity in nanocrystalline system, we should not have observed the 550 °C anomaly based on the conclusion mentioned earlier. This result may lead to reconsideration of Goman'kovs'¹⁰ suggestion which propose that anomaly arises by the appearance of magnetic dispersion in the superstructural reflection caused by the difference in partial magnetic moments at temperatures above the anomaly temperature.

IV. CONCLUSION

We have successfully produced $\text{Fe}_x\text{Co}_{1-x}[\text{C}]$ nanoparticles with a disordered bcc structure by plasma torch synthesis. Reordering of this as-quenched nanoparticles was observed with thermomagnetic measurements. No compositional dependence of this reordering temperature was observed due to the fact that high diffusivity in this particle dominates over the compositional effect. The so-called 550 °C anomaly was observed as a decrease in saturation magnetization even with the lower heating rates, i.e., 2 °C/min.

LaCo_{13} and $\text{La}(\text{Co}, \text{Fe})_{13}$ alloys have been prepared and studied as high temperature, high performance soft magnetic materials. The dc magnetic properties have been measured over a temperature range of 10–1273 K in fields of 0 to 5 T. Data obtained show that the dc magnetic properties (H_c, K_1) of the $\text{La}(\text{Co}, \text{Fe})_{13}$ bulk alloys are comparable with Fe bulk alloy and $T_c = 1021\text{--}1297$ K are higher than that of Fe and Hipercor; ac magnetic properties are first time reported in a bulk LaCo_{13} alloy, showing a reasonably higher power loss than that of commercial Hipercor alloy. The ac magnetic properties can be improved by making LaCo_{13} alloys as laminated thin sheets. © 1998 American Institute of Physics. [S0021-8979(98)29311-X]

I. INTRODUCTION

LaCo_{13} has a high content of the 3d element Co which leads to a large magnetization (1.3 T) and a high T_c (1297 K).¹ Because of these properties, this alloy has attracted attention in regard to high temperature applications. It had been studied in this laboratory some years ago as a hard magnetic material. Results were negative in that regard.² In the present investigation, LaCo_{13} -based alloys have been studied as soft magnetic materials. Their cubic structure leads to the low anisotropy and coercivity, which is required by a soft magnetic material. This article provides information in regard to the basic soft magnetic properties, both dc and ac, for LaCo_{13} -based alloy systems. LaCo_{13} and $\text{La}(\text{Co}, \text{Fe})_{13}$ alloys have been synthesized and characterized in a bulk form. The dc magnetic properties have been measured over the temperature range of 10 to 1273 K in fields from 0 to 5 T. The ac magnetic properties are established at room temperature in the frequency range of 50 Hz to 100 kHz. The magnetocrystalline anisotropy constant K_1 has been estimated based on the law of approach to saturation.

II. EXPERIMENTAL DETAILS

The alloys were prepared by arc melting under argon, after which they were heat treated at 1273 K for about one week. X-ray diffraction (XRD) with Cu radiation was used to determine crystal structure and lattice parameters. The dc magnetic properties (M , T_c , H_c , and K_1) were established using a vibrating sample magnetometer (VSM) and a superconducting quantum interference device magnetometer (SQUID) with a chunk sample. The ac magnetic properties were established using a hysteresisgraph (Walker AMH-401) with a toroidal sample which was cut from a bulk ingot. The dimensions of the toroidal sample are o.d. (1.5 cm), i.d. (0.9 cm), path (3.77 cm), and area ($0.3 \times 0.3 \text{ cm}^2$).

III. RESULTS AND DISCUSSIONS

A. Structure and dc magnetic properties

The structure and dc magnetic properties M_s , H_c , and T_c are given in Table I and Fig. 1. The results show that the LaCo_{13} sample is single phase with the fcc NaZn_{13} structure. It exhibits no phase transition between RT and 1300 K, except a magnetic transition (ferro to para) at the Curie temperature (1297 K). The coercivity, H_c , for a polycrystal bulk sample of the LaCo_{13} alloy is ~ 8 Oe at RT and ~ 10 Oe at 10 K. It is comparable with a pure Fe sample, the H_c of which is around 5 Oe for a bulk material. Above room temperature, H_c of the LaCo_{13} alloy decreases almost linearly with increasing temperature. At 800 °C, it is about 30% reduced from that at room temperature (see Fig. 1). This behavior can be ascribed to the decrease of magnetocrystalline anisotropy energy with increasing temperature. The moment of LaCo_{13} alloy at RT, 130 emu/g, is lower than that of Fe and Fe–Co alloys. However, the moment can be enhanced by partial replacement of Co with Fe. As shown in Table I, a sample with $\sim 40\%$ Fe substitution, has a moment of 153 emu/g at RT and 159 emu/g at 10 K. This alloy retains the fcc structure of the LaCo_{13} alloy and shows a similar low H_c , around ~ 8 Oe at RT and ~ 10 Oe at 10 K.

B. Magnetocrystalline anisotropy constant K_1

Making use of the law of approach to saturation for polycrystalline material with crystals oriented at random and also in cubic structure,³

TABLE I. Structure and dc magnetic Properties of LaCo_{13} -type alloys.

Compound	Structure	a (Å)	M (emu/g) ^a		H_c (Oe)		T_c (K)
			RT	10 K	RT	10 K	
LaCo_{13}	NaZn_{13}	11.340	130	135	~ 8	~ 10	1297
$\text{La}(\text{Co}_{0.6}\text{Fe}_{0.4})_{13}$	NaZn_{13}	11.469	153	159	~ 8	~ 10	1021

^{a)}Measured at $H = 5$ T.

FIG. 1. The dc-coercivity H_c vs temperature T for LaCo_{13} ($H=1.6$ T).

$$I_s = I_s \left(1 - \frac{a}{H} - \frac{b}{H^2} - \dots \right) + \chi_0 H,$$

$$\frac{dI}{dH} = I_s \left(\frac{a}{H^2} + \frac{2b}{H^3} + \dots \right) + \chi_0, b = \frac{8}{105} \frac{K_1}{I_s^2}$$

we have estimated a magnetocrystalline anisotropy constant K_1 for a LaCo_{13} sample. The sample is in a cube shape. Considering the effect of a demagnetizing field created by the magnetic poles of this cube sample on our measurement, a demagnetizing factor $N=0.27$ has been used. It is taken from Bozorth's demagnetizing factor calculation data for a rod-shape sample with length/diameter=1.⁴ From experiment results of moment I (G) vs field H (Oe), we can obtain dI/dH vs $1/H^3$ (see Fig. 2). Then, from the slope of this curve, $2bI_s = 16K_1^2/105I_s$, we have estimated a value of $K_1 \sim 3.5\text{--}6 \times 10^5$ erg/cm³, which is comparable with K_1 of Fe, 4.5×10^5 erg/cm³.

C. The ac magnetic properties

The information about the ac magnetic properties of the LaCo_{13} toroidal sample are given in Figs. 3–8.

Figure 3 shows typical ac-(BH) loops, measured at different frequencies (50 Hz–5 kHz). Maximum induction B_m , coercivity H_c vs maximum field H_m at 50–400 Hz and total core loss per unit mass P_{cm} vs B_m are given in Figs. 4 and 5. The B_m is around 10 kG at 50 and 400 Hz. The H_c increases from ~ 12 to ~ 27 Oe when frequency increases from 50 to 400 Hz. The total power loss at 400 Hz is around 0.2 W/g for $B_m = 10$ kG (see Fig. 5). It is much higher than that of a current commercial Hiperco 50 sample, which is 0.01 W/g for $B_m = 10$ kG at 400 Hz.⁵ This high power loss was expected, especially due to the eddy current loss. As we know,^{4,6} the macroscopic eddy current loss is proportional to

FIG. 2. dI/dH vs $1/H^3$ for LaCo_{13} . (I -moment per volume).FIG. 3. ac-BH loops measured at 50 Hz–5 kHz for LaCo_{13} .FIG. 4. B_m , H_c vs H_m at 50 and 400 Hz for LaCo_{13} .FIG. 5. P_{cm} (core loss per gram) vs B_m (flux density) at 50–400 Hz for LaCo_{13} .FIG. 6. $2\pi(\mu''/\mu')/\mu_i$ (specific loss factor) vs f at B_m of 0.1–1 kG.

FIG. 7. P_{cm}/f (core loss per cycle) vs f (frequency) at $B_m=4-8$ kG.

$(fBr)^2/\rho$, where f is the frequency, B is the induction, ρ is the resistivity, and r is the radius of the cylinder or the thickness of the plate of the materials. Comparing the dimensions of the LaCo_{13} sample with the Hiperco sample, which is made of laminated thin sheets and the thickness of the each sheet is ~ 0.015 cm, the $r \sim \sqrt{(0.09)\text{cm}^2/\pi} \sim 0.17$ cm for the LaCo_{13} sample is almost 11 times larger than that of the Hiperco sample. By this factor, the eddy-current loss for the LaCo_{13} sample could be 100 times higher than that of the Hiperco sample. Except for the eddy current loss, the total power loss also involves a hysteresis loss and a residual loss.⁴ By using classic methods,⁴ we can analyze and separate these three type of losses.

1. Power losses analysis

a. *Losses in low inductions:* ($B_m=0.1-1$ kG, $f \leq 500$ Hz): Legg⁷ gave an empirical equation expressing the losses in low fields: $2\pi(\mu''/\mu')/\mu_i = ef + aB + c$, where $(\mu''/\mu')/\mu_i$ is the specific loss factor, μ' is the real part, and μ'' is the imaginary part of the complex permeability, μ_i is the initial permeability, 167, which was obtained from dc measurement by using Walker dc hysteresisgraphy in a cylinder sample at this lab, e is the eddy-current resistance coefficient, a is the hysteresis resistance constant, and c is residual loss constant. We have measured the frequency dependence of $2\pi(\mu''/\mu')/\mu_i$ at different B_m , 0.1–1 kG (in Fig. 6). The values of e , a , and c can be established as follows: (1) $e \sim 4.8 \times 10^{-5}$ s, which is around four orders of magnitude higher than that of Hiperco 80 alloys (10^{-9}).⁸ (2) $a \sim 1.3 \times 10^{-5}$ G⁻¹, which is a same order of magnitude with that of the Hiperco 80 (10^{-5}). (3) $c \sim 5600 \times 10^{-6}$, which is a same order of magnitude as ferrite materials.⁸

b. *Losses at intermediate and high inductions:* ($B_m=0.3-0.8$ kG, and $f \leq 100$ Hz). Using the Steinmetz equation for hysteresis losses,⁴ the total power losses are as follows: $P = \eta B^{1.6}f + eB^2f^2$, or P/f (power losses per cycle) $= \eta B^{1.6} + eB^2f$, where $\eta B^{1.6}$ is the hysteresis loss per cycle and eB^2f is the eddy current loss per cycle. We have measured the frequency dependence of core loss per cycle at $B_m=4-8$ kG and plotted P/f vs f for different B_m , (in Fig. 7). From these experimental curves, one can established η and e . The results are: $e \sim 1.2 \times 10^{-6}$ s, and $\eta \sim 6 \times 10^{-3}$ Oe. Using these two constants, we can analyze the relative loss of eB^2f^2 and $\eta B^{1.6}f$. For example, to obtain

FIG. 8. Frequency dependence of the real (μ') and imaginary (μ'') parts of the complex permeability at $H_m \sim 25$ Oe.

$B_m \sim 8$ kG at $f \sim 400$ Hz for the LaCo_{13} sample, the eddy current loss, eB^2f^2 , is 79% of the total loss, which dominates the power loss, and the hysteresis loss is only 21%. Usually, η is related to coercivity H_c of materials, i.e., $\eta \sim 10^{-3} H_c$. Our experimental results, H_c , measured at $B_m \sim 8$ kG and $f \leq 100$ Hz, are 7–8 Oe, which agree with the above estimation.

2. Magnetic spectrum (μ' , μ'' vs f)

At the ac magnetic field, the magnetic induction B is generally delayed by the phase angle δ from the magnetic field H due to various types of power losses and resonances. $B = \mu H = (\mu' - j\mu'')H$, where μ' and μ'' express the real and imaginary parts of the complex permeability μ , respectively. The physical mechanism of this lag due to different types of resonances can be studied by analyzing a magnetic spectrum (μ' and μ'' vs f at a low ac field). Figure 8 shows a magnetic spectrum of the LaCo_{13} sample, which was measured at a lower field (~ 25 Oe). This curve shows a relaxation type of magnetic spectrum.⁹ At ~ 400 Hz, the μ' drops and μ'' increases rapidly and reaches a maximum, as well as the energy loss of the sample. It can be suggested that a resonance of domain wall motion occurs at ~ 400 Hz. A maximum application frequency (cutoff f) for the LaCo_{13} sample is around ~ 750 Hz, where μ' drops to \sim half of μ_{\max} , and it is lower than that of the Hiperco alloys (~ 1 kHz).

Effects of heat treatment on the magnetic properties of polymer-bound iron particle cores

M. Namkung, B. Wincheski, and R. G. Bryant
NASA Langley Research Center, Hampton, Virginia 23681

A. Buchman
Old Dominion University, Norfolk, Virginia 23529

Spherical iron particles of three different size distributions, 6–10 μ in diameter, 100 mesh and 30–80 mesh, were mixed with 2.0 wt % of soluble imide and compression molded at 300 °C under 131 MPa. Post-fabrication heat treatments were performed at 960 °C for 6 h resulting in a significant enhancement of the permeability in low field region for all the specimens except for the one made of 30–80 mesh particles. The rate of core loss of these specimens at a magnetic induction of 5 kG measured up to 1 kHz shows a noticeable increase after heat treatment which, along with the permeability enhancement, can be explained by the coalescence of particles forming a network of conductivity paths in the specimens. The scanning electron micrographs taken for the 6–10 μ particle specimens show no evidence of heat treatment-induced grain growth. The untreated specimens show a very weak f^2 -dependence of the core loss which clearly indicates a negligible contribution from the eddy current loss. In particular, an almost perfect linearity was found in the frequency dependence of the core loss of the untreated specimen made of 100 mesh iron particles.

© 1998 American Institute of Physics. [S0021-8979(98)34711-8]

I. INTRODUCTION

Our previous study has shown that the permeability of polymer-bound cores of spherical iron particles of 6–10 μ can be enhanced by a factor of 30–40 through a simple post-fabrication heat treatment at 960 °C for 6 h.¹ The low field portion of the magnetization curves of these heat treated specimens showed clear evidence of contributions from reversible and irreversible domain wall motions which were absent in the untreated specimens. The most probable reason for such a heat treatment-induced permeability enhancement is the coalescence of iron particles forming a network connecting bare metal particles since the temperature of heat treatment was within the range of the typical sintering temperature of metallic particles.

Unlike the case of sintered powder metallurgy components, the presence of polyimide in these core specimens does not allow a clear visualization of interparticle contacts in the scanning electron micrographs. An alternate way of investigating the formation of such a network structure is to measure the core loss which is sensitive to the range of eddy current flow. Hence, the purpose of the present study is to systematically investigate the effect of heat treatment on the core loss for specimens of different size distributions since it is one of the major factors controlling the structure² upon which the magnetic properties of interest depend.

II. EXPERIMENTS

Spherical iron particles of 6–10 μ in diameter, 30–80 mesh (0.59–0.17 mm in diameter) and 100 mesh (diameter less than 0.14 mm) were mixed with 2.0 wt % of high temperature soluble thermoplastic adhesive known as LaRC™-SI and molded into cubic blocks under 131 MPa of external compressive load at 300 °C for 30 min.³ Two pic-

ture frame specimens of identical geometry having a cross-section of 6.35×6.35 mm², and outer edges of lengths 12.7 mm and 19.05 mm were cut from each block for core loss measurements. One of the two picture frame specimens of each particle size distribution was heat treated at 960 °C for 6 h. The rate of heating and cooling before and after heat treatment in the furnace was approximately 0.5 °C/min. The core loss was measured at the magnetic induction amplitude of 5 kG up to 1 kHz except the heat treated specimens of 6–10 μ and 30–80 mesh particles which were tested to 500 Hz. Two identical square rod specimens with the same cross-section of 6.35×6.35 mm² and 19.05 mm length were prepared from each block for the characterization of permeability, mass density and conductivity before and after an identical heat treatment.

III. RESULTS AND DISCUSSION

Figure 1 summarizes the magnetization curves of untreated and heat treated specimens of the three particle size distributions. The magnetization of the three untreated specimens increases very slowly but maintains its slope in the high field region, i.e., roughly 170–500 Oe, which is steeper than that of heat treated specimens of 6–10 μ and 100 mesh particles. This indicates that a certain level of domain wall motion is present in the untreated specimens in this field region. This is readily explainable since most iron particles are coated and well isolated in these untreated specimens providing strong barriers impeding the domain wall movement such that it takes a stronger driving force to complete the domain wall motion.⁴ The effect of heat treatment on the 6–10 μ particle specimen is seen to be dramatic. A close examination of the initial stage reveals the domain wall mobility for reversible motion is even higher in the heat treated

FIG. 1. Magnetization curves of heat treated (filled symbols) and untreated (unfilled symbols) specimens of three different iron particle size distributions.

specimen of 100 mesh particles than it is in that of 6–10 μ particles but the overall induction being much lower in the former is not immediately explainable. It is evident that the effect of heat treatment on the dc magnetic properties of the 30–80 mesh particle specimens is merely to increase the magnetization.

Speed and Elman showed that prefabrication annealing of the iron particles increase the maximum permeability by a factor of 2–5⁴ which is presumably due to relieving of the surface residual stress in each particle that tends to limit the magnetization activity. The temperature of molding in the present work, i.e., 300 °C, is not high enough for residual stress relief. The temperature of post-fabrication heat treatment, 960 °C, is in the range of typical sintering temperature and it is safely assumed that the individual particles are stress-relieved and coalesced with the neighboring ones forming a channel which enhances the domain wall mobility. Hence, the post-fabrication heat treatment provides two major effects enhancing the initial magnetization processes observed in the 6–10 μ and 100 mesh specimen. An indirect evidence of coalescence of particles is the brittle-ductile transition introduced by the heat treatment as reported in our previous study.¹ The behavior of initial magnetization of the heat treated 30–80 mesh specimen is not readily explainable and the rupture test of this specimen, which is yet to be performed, may provide useful information.

Table I summarizes the density and resistivity of the test

TABLE I. Density and resistivity of test specimens.

Specimens ^a	Density ^b (gm/cc)	Resistivity (Ω cm)
6–10 μ	6.3 ^c /6.22 ^d	0.467/0.043
100 mesh	5.88/7.41	1.686/0.057
30–80 mesh	5.75/6.92	0.161/0.064

^bDensity measured using the weight of an object measured immediately after it was submerged in water. (It changes as water fills up the voids. See Ref. 1 for details.)

^cValues for untreated specimens.

^dValues for heat treated specimens.

FIG. 2. Frequency dependent core loss/unit mass of heat treated (square) and untreated (circle) specimens of 6–10 μ iron particle cores.

specimens measured before and after heat treatment. The density of the 6–10 μ specimen in this work was reduced by heat treatment which is a trend that is consistent with that reported in the previous work.¹ Such a reduction in the density is thought to be due to the bubbling up of the binder material, i.e., polyimide, creating voids but why it is limited to 6–10 μ particles only is yet to be studied further. The resistivity of the 6–10 μ particle specimen is seen to decrease by a factor of 10 due to heat treatment. Such a reduction in the resistivity can be clearly explained. The individual particles were originally coated with polyimide. During the fabrication process, at 300 °C under 131 MPa of compressive load, however, a certain fraction of particles rub against each other establishing bare metal to metal contacts forming an initial stage of network through the specimen. The heat treatment causes the neighboring particles in direct contact to coalesce into each other to drastically reduce the resistivity in the conduction network. In addition, the carbonization of polyimide, which begins to occur around 500 °C, transforms the insulating layers among the particles into a conducting matrix.

The density and dc magnetic properties are closely related to the particle size distribution and the fabrication condition. For certain simplified conditions, it is possible to numerically predict both properties.⁵ The presence of the binder, however, causes significant complication and no particular correlation can be found. Nevertheless, all the heat treated specimens display consistently low resistivity values. It is to be noted that the resistivity of the untreated 100 mesh particle specimen is much higher than those of the other specimens. Figure 2 shows the core loss of heat treated and untreated 6–10 μ particle specimens. It is immediately clear that the nonlinear frequency dependence is very weak in the loss curve of the untreated specimen, whereas a noticeable nonlinearity is present in the curve of the heat treated specimen. The simplest model of frequency dependence of core loss includes two terms; first and second order terms of frequency. The former is due to the hysteresis loss and the latter is due to the eddy current loss assuming the absence of the domain structure. Figure 3 shows a nonlinear curve of core loss per kg-cycle as a function of frequency of the heat

FIG. 3. Nonlinearity in core loss/unit mass-cycle in 6–10 μ iron particle core indicating the effect of anomalous eddy current loss due to a nonuniform distribution of magnetization across the cross-section.

treated 6–10 μ particle specimen displaying the effect of anomalous eddy current loss caused by the presence of domain wall motion.⁴

Figure 4 shows the core loss of heat treated and untreated specimens of 100 mesh particles. The core loss of the untreated specimen is seen to be a remarkably linear function of frequency which is a clear evidence of the absence of eddy current loss in this material. When fitted to a second order polynomial, the coefficients of the second and first order of frequency terms are $5.8149 \times 10^{-8} \text{ W s}^2/\text{gm}$ and $1.4975 \times 10^{-6} \text{ W s}/\text{gm}$, respectively. Compared to $1.269 \times 10^{-6} \text{ W s}^2/\text{gm}$ and $2.187 \times 10^{-6} \text{ W s}/\text{gm}$ for the curve of heat treated specimen, the linearity in the untreated specimen can be considered nearly perfect. The lack of eddy current loss is a strong evidence of the absence of macroscopic eddy current flow in the material since the effect of microscopic

FIG. 4. Frequency dependent core loss/unit mass of heat treated (square) and untreated (circle) specimens of 100 mesh particles displaying a nearly perfect linearity in the latter due to the absence of eddy current loss.

FIG. 5. Frequency dependent core loss/unit mass of heat treated (square) and untreated (circle) specimens of 30–80 mesh iron particles.

eddy current contribution is linearly proportional to the frequency.⁶ Figure 5 shows the results of core loss measurements in 30–80 mesh particle specimens. The difference in core loss between heat treated and untreated states in these specimens is as pronounced as in the specimens of 6–10 μ particles.

It is evident that the core loss is noticeably lower in the untreated specimens than in the heat treated specimens as the frequency increases. Apparently, the major contributing factor for this is the resistivity. The resistivity of the untreated 100 mesh iron particle specimen, in particular, is unusually high and it contributes to the elimination of eddy current loss. At the same time, the magnetization curve of this specimen is comparable to those of the two other untreated specimens. As high resistivity and magnetization are essential requirements for a transformer core material, the untreated 100 mesh iron particle specimen provides a clear direction for the further development.

IV. CONCLUSION

The effect of heat treatment on the magnetization and core loss properties were investigated in polymer-bound iron particle cores of three different particles size distributions. It was found that the iron particle size distribution strongly affects the heat treatment-induced enhancement of magnetization as well as the frequency dependence of core loss which was investigated up to 1 kHz. The absence of eddy current loss, which was attributed to high resistivity, was observed in the untreated 100 mesh iron particle specimen.

Alternating current magnetic properties of cores made from pressed acicular steel particles

R. F. Krause,^{a)} J. H. Bularzik, and H. R. Kokal
Magnetics International, Inc., Burns Harbor, Indiana 46304

This article describes results of magnetic testing of cores made from a composite material that yields powder metallurgically pressed compacts of high density suitable for a variety of ac magnetic applications. Small acicular steel particles are annealed, individually insulated, and uniaxially pressed using standard powder metallurgical techniques. The ac losses and permeability of the pressed compacts are strongly dependent upon particle geometry. The variations of the core loss among the different particle geometries was found to be a function of the cross sectional area of the acicular particles as well as the strain imparted to the particles during the pressing operation. The core loss, when measured at 60 Hz, exhibits a minimum at a certain cross sectional area. The shape of the curve is attributed to a decrease in eddy current loss with decreasing particle cross sectional area, while the hysteresis loss increases with decreasing particle cross sectional area. At a test frequency of 400 Hz, the eddy current component of core loss predominates, and the core loss decreases steadily with decreasing particle cross sectional area. Permeability was also found to depend upon particle geometry. The smaller the demagnetizing factor of the individual particles, the higher the permeability, while the increased strain in the smaller particles overwhelms the smaller demagnetizing factor resulting in a decrease in permeability. The net result is a maximum in permeability for the mid-sized particles. © 1998 American Institute of Physics. [S0021-8979(98)22211-0]

I. INTRODUCTION

Pressed cores made from insulated iron powders have been used for many years for ac magnetic applications.¹ These “dust cores” and similar flake iron cores are particularly applicable for very high frequency applications, up to 1 MHz. Unfortunately, because of the nature of the very fine particle size, the density of both dust cores and flake iron cores is rather low, therefore, the magnetic properties are not suitable for power frequency applications. Recently, there has been a resurgence of interest in the development of “composite” materials consisting of iron powders with organic coatings.²⁻⁶ Unfortunately, the low density and low frequency properties are still insufficient for use in most devices that operate at power frequencies.

This article discusses results of magnetic testing of a composite soft magnetic material that has been developed for power and low frequency ac magnetic applications.⁷⁻⁹ This composite material consists of acicular steel particles that are annealed, individually insulated with an organometallic insulation, lubricated to enable pressing using conventional powder metallurgical techniques, and pressed to final shape in a die. The resultant cores have a very high density ($7.50\text{--}7.70\text{ g/cm}^3$), approximately equivalent to the density of a stack of steel laminations.

Variables that can influence the magnetic properties include particle properties such as composition, size, and shape, and the processing parameters such as coating thickness, annealing conditions, and pressing pressure. It has been found that the geometry of the particles is particularly important if acceptable ac properties are to be obtained. Specifically,

these acicular particles are roughly triangular in cross section and several orders of magnitude larger than typical powdered iron. This article discusses the effect of particle geometry on the magnetic properties.

II. EXPERIMENTAL PROCEDURE

Steel particles were produced with different cross sectional areas but with the same particle length ($\sim 0.2\text{ cm}$). The cross sectional areas ranged from about $4.6 \times 10^{-4}\text{ cm}^2$ for the smallest particle to about $2.5 \times 10^{-3}\text{ cm}^2$ for the largest particle. All particles were annealed, received the same amount of insulative coating, the same amount of lubricant, and the same pressing pressure (860 MPa) when pressed into test cores. The test cores are approximately 1.1 cm in height with an inside diameter of approximately 2.5 cm and an outside diameter of approximately 5.0 cm. After pressing, the lubricant was baked out of the cores at 315°C . The compact density was approximately 7.70 g/cm^3 or about 98% of the theoretical density of iron. The ac magnetic properties, core loss and permeability, were measured at frequencies of 60, 100, and 400 Hz.

From a classical point of view, the total core loss consists of hysteresis loss and eddy current loss. The hysteresis loss is considered to vary linearly with frequency, while the eddy current loss varies with the square of the magnetizing frequency. Plotting the loss per cycle versus frequency allows one to separate the loss into the classical components.

III. RESULTS AND DISCUSSION

The effect of the cross sectional area of the particles on the core loss is shown in Fig. 1. A minimum in 15 kG, 60 Hz core loss occurs at a particle cross sectional area of about $1.4 \times 10^{-3}\text{ cm}^2$. The 15 kG, 400 Hz core loss does not exhibit a similar minimum within the range of particle sizes

^{a)}Electronic mail: Krause@inland.com

FIG. 1. Effect of cross sectional area on 15 kG, 60 Hz, and 400 Hz core loss.

studied. Instead, the core loss steadily decreases as the particle cross sectional area decreases. The 15 kG, 100 Hz core loss, which is not shown, exhibits a minimum at a particle cross sectional area of approximately $1.2 \times 10^{-3} \text{ cm}^2$. Thus, within the range studied, the minimum core loss occurs with ever decreasing particle size as the test frequency increases. These results can be explained by understanding the contribution of both the hysteresis losses and the eddy current losses in the different sized particles.

Using an analogy between lamination steels where the eddy current loss is proportional to the sheet thickness squared,¹⁰ the eddy current loss of these small particles would be expected to decrease as the thickness (or cross sectional area) of the particles decreases. Figure 2 presents the slope of the eddy current loss with frequency versus the cross sectional area of the particles. The eddy current loss

FIG. 2. The dependence of 15 kG eddy current loss on particle cross sectional area.

FIG. 3. The dependence of 15 kG hysteresis loss on particle cross sectional area.

steadily declines with decreasing particle cross sectional area. Thus, the analogy between lamination steel and these small particles appears justified.

The hysteresis loss is dependent upon many factors. Some of these factors, such as chemical composition, are the same for all particle sizes in this experiment. Yet other factors can be different, such as the degree of plastic deformation that occurs in the particles during the pressing operation and the surface area of the individual particles. Again, drawing an analogy with lamination steel where the hysteresis loss increases as the thickness of the sheet decreases (or as the surface-to-volume ratio increases) we would expect that the hysteresis loss would increase as the particle cross sectional area decreases. Figure 3 presents the 15 kG hysteresis loss as a function of particle cross sectional area. The hysteresis loss does in fact decrease as the particle cross sectional area increases and appears to level off for the very large particles. As discussed above, this behavior is not unexpected.

FIG. 4. Effect of cross sectional area on 15 kG permeability.

FIG. 5. Planar anisotropy (highly stylized).

If Figs. 2 and 3 are compared, it is now evident why the core loss behavior illustrated in Fig. 1 is observed. Typically, hysteresis loss is said to increase linearly with frequency while classical eddy current loss increases with the square of frequency.¹⁰ Thus, in the low frequency regime, a minimum in core loss occurs. However, as the test frequency increases, this minimum shifts to ever decreasing particle cross sectional areas as the eddy current component of the total losses begins to predominate.

The effect of particle cross sectional area on the 15 kG permeability is illustrated in Fig. 4. A maximum in permeability occurs at a particle cross sectional area of about $1.5 \times 10^{-3} \text{ cm}^2$. This behavior is thought to be dependent upon two competing processes: (1) the shape anisotropy of the individual particles and (2) either the strain induced by pressing or the surface-to-volume ratio of the individual particles. Hysteresis loss and permeability should be closely related since both measure the "softness" of a magnetic material. That is, the lower the hysteresis loss, the higher the permeability. Previously, it was hypothesized that the hysteresis loss increases with decreasing particle cross sectional area because the degree of plastic deformation that occurs in the particles during the pressing operation might be more severe in the smaller particles, and the surface-area-to-volume ratio of the individual particles is greater in the smaller particles. Thus, if this hypothesis is true, the permeability should decrease with decreasing particle size.

Competing with the behavior described above is thought to be the shape anisotropy of the individual particles. Since the particles are acicular in shape, they will tend to have their major axes lie perpendicular to the pressing direction when they are placed (or fall) into the pressing cavity, Fig. 5. Thus, an overall shape anisotropy is created in the pressed compact. This anisotropy will affect the apparent permeability of the compact.¹¹ For simplicity, we can think of these acicular particles as small rods, each with a shape anisotropy related directly to their aspect ratio. Since all particles are of the same length, the particles with the smallest cross sectional

area will exhibit the lowest demagnetizing factor. Thus, if a single particle is magnetized along its axis the apparent permeability will be dependent upon the demagnetizing factor of that particle, i.e., the smaller the cross sectional area of the particle, the higher the apparent permeability. Translating the effect into the pressed compact would suggest that the compacts made from the particles with the smallest cross sectional area would exhibit the highest permeability. It is suggested that these competing effects account for the behavior exhibited in Fig. 4.

IV. SUMMARY

The ac magnetic properties of composite cores pressed from insulated acicular particles have been measured. It has been found that the size of the particles strongly influences the magnetic properties of the pressed cores. Particles with a small cross sectional area exhibit a small eddy current loss but a high hysteresis loss, while particles with a large cross sectional area exhibit just the opposite. Thus, the minimum core loss as a function of frequency is strongly dependent on particle geometry. Permeability was also observed to be dependent on particle geometry and this can be explained qualitatively in terms of a net shape anisotropy in the pressed cores and plastic deformation during pressing.

J. S. Woo

Research Laboratory, Pohang Iron and Steel Company, Pohang 790-785, Korea

A correlation between magnetic induction and surface phenomena has been investigated in a 3% Si steel 0.1 mm thick. During final annealing at several temperatures, the saturation level in magnetic induction increased with increasing final annealing temperature, and reached 1.93 T after final annealing at 1300 °C for 4.9 ks. This is attributed to the formation of complete (110)[001] Goss texture. During final annealing, the magnetic induction of the thin-gauged 3% Si strip was inversely proportional to the sulfur concentration on the surface. The surface segregation of sulfur occurred after a critical time the silicon concentration on the surface dropped to the level obtained from the α -iron matrix containing 3% Si. The drop in silicon level on the thin-gauged strip surface is due to the volatile silicon monoxide, which arises from the reaction between the silicon dioxide and the silicon segregated, or between the silicon segregated and the oxygen from the high vacuum condition. © 1998 American Institute of Physics. [S0021-8979(98)41511-1]

I. INTRODUCTION

A 3% Si steel with (110)[001] Goss texture, which results in high magnetic induction, is usually used as core materials of power and distribution transformers. There are indications that adsorption of sulfur, and possibly oxygen, on silicon steels can lead to the development of (100)[001] texture in thin sheets by a surface-energy induced recrystallization process.¹⁻³ For a clean surface (i.e., the absence of sulfur or oxygen) (110)[001] texture develops. It is the purpose of this study to investigate the correlation between surface phenomena during final annealing and the magnetic induction in a 3% Si steel 0.1 mm thick.

II. EXPERIMENTAL PROCEDURE

A 3% Si steel was prepared through vacuum induction melting. The chemical composition of the steel is shown in Table I. The ingot was hot-rolled to 2.5 mm plates after holding at 1200 °C for 3.6 ks. The thickness of the plates were finally reduced to 0.1 mm through three-steps cold rolling process with a reduction ratio of 80%–50%–60%. During cold rolling process intermediate annealing was performed at 800 °C for 1.8 ks. The final annealing was given the thin strips in the temperature range of 1000–1300 °C for 0.02 to 184.2 ks. All the annealing treatments were carried out under a vacuum of approximately 10^{-6} Torr. Auger electron spectroscopy (AES) was used for surface analyses. Surface phenomena on the thin-gauged 3% Si strips during final annealing were investigated with ion sputtering technique after final annealing, although this method is not accurate in finding the real Auger peaks because the ion sputtering technique tends to spread out artificially the solute atom distribution in the direction of the beam.⁴

III. RESULTS AND DISCUSSION

Figure 1 shows a change in magnetic induction of the thin-gauged 3% Si strip with final annealing time at 1200 °C. Here, one sample was only used, and was repeatedly annealed to 14.4 ks in order to obtain the magnetic induction values shown in Fig. 1. During final annealing, the magnetic induction [$B_{10}(T)$] passed through a maximum and a minimum, and then increased up to 1.90 T after final annealing to 14.4 ks. The magnetic induction, however, amounted to 1.98 T after one-step final annealing for 14.4 ks. The result of ion-sputtering is shown in Fig. 2, which has been obtained from the sample finally annealed at 1200 °C for 0.06 ks. Prior to ion-sputtering, strong oxygen and carbon peaks were observed while sulfur peak was very weak. After ion-sputtering for 0.015 ks, the carbon adsorbed on the surface from atmosphere was removed, but the oxygen peak became stronger, relatively. This result may imply the presence of an iron oxide layer of atomic scale on the surface, which can be supported by the data.⁵ A sulfur peak appeared with increasing ion-sputtering time, and showed a maximum after ion-sputtering for 0.045 ks. It is suggested that the position corresponding to the maximum is approximately located at the real surface of the thin-gauged strip exposed to the final annealing condition. Figure 3 shows a change in sulfur concentration on the thin-gauged strip with final annealing time at 1200 °C. After final annealing for 0.18 ks, the sulfur concentration reached a maximum, and then decreased to a low level with increasing annealing time. It is shown from a com-

TABLE I. The chemical composition of the thin-gauged 3% Si steel.

Si	C	S	N	Mn
2.92	0.002	0.0006	0.0013	<0.001

FIG. 1. A change in magnetic induction of the thin-gauged 3% Si steel strip 0.1 mm thick with accumulative final annealing time at 1200 °C.

parison between Figs. 1 and 3 that the maximum in sulfur concentration corresponds to the minimum in magnetic induction, and the magnetic induction increases to the saturation point with decreasing sulfur. This result is in good agreement with the results of some other researches,^{6,7} which reported that the segregated sulfur on surface was the main factor inhibiting the formation of (110)[001] Goss texture.

It has been reported that the segregation kinetics of a species is largely influenced by a precipitation reaction related to the segregating species^{8,9} or by evaporation occurring at a solid-vapor or solid-vacuum interface.^{10,11} Lea and Seah¹¹ found evaporation of tin to be significant in their Auger study of surface segregation kinetics in an Fe–Sn system, and treated the free surface segregation including evaporation theoretically. Following their result, the surface coverage at short times increases as if there were no evaporation. With increasing time, the evaporative loss term becomes dominant so that the surface coverage passes through a maximum, and then decreases to a very low value. Likewise, such a maximum appears also in segregation kinetics accompanying a precipitation reaction.^{8,9} Considering the extremely high vapor pressure of sulfur,¹² such an evaporation phenomenon can possibly occur in the present annealing condition. As a result, the maximum point in sulfur concentration, as shown in Fig. 3, means a turning point, after which the evaporation of sulfur becomes dominant, relatively.

FIG. 2. Ion-sputtering result obtained from the sample finally annealed at 1200 °C for 0.06 ks.

FIG. 3. A change in sulfur peak with accumulative final annealing time at 1200 °C.

Figure 4 shows changes in magnetic induction of the thin-gauged strips during final annealing at several temperatures. At early annealing stage of each temperature, the abrupt increase in magnetic induction can mainly be attributed to the effect of stress relief. The saturation level in magnetic induction increased with increasing final annealing temperature, and amounted to 1.93 T after annealing at 1300 °C for 4.9 ks. However, the saturation value in magnetic induction, 1.71 T, obtained after final annealing at 1000 °C for 184.2 ks was much lower than that at 1300 °C. Ion-sputtering results obtained from the samples finally annealed at 1000 °C for 3.6 and 91.7 ks are shown in Figs. 5(a) and 5(b). As shown in Fig. 5(a), the sulfur segregated is not observed within the ion-sputtering time range, while the silicon and oxygen peaks are strong and decrease gradually with ion-sputtering time. The silicon peak decreased with final annealing time at 1000 °C and dropped to the level obtained from the bulk matrix after final annealing for 91.7 ks as shown in Fig. 5(b). The sulfur peak appeared after the drop of the silicon peak. Based on the results,^{13–15} the drop in the silicon peak during final annealing at 1000 °C can be explained as follows. During heating to the final annealing temperature, the silicon segregated reacts rapidly with oxygen in the high vacuum, resulting in silicon dioxide. Subsequently, during final annealing at the temperature, the silicon dioxide reacts with the silicon segregated from the matrix, giving the

FIG. 4. Changes in magnetic induction of thin-gauged strips with accumulative final annealing time at several temperatures.

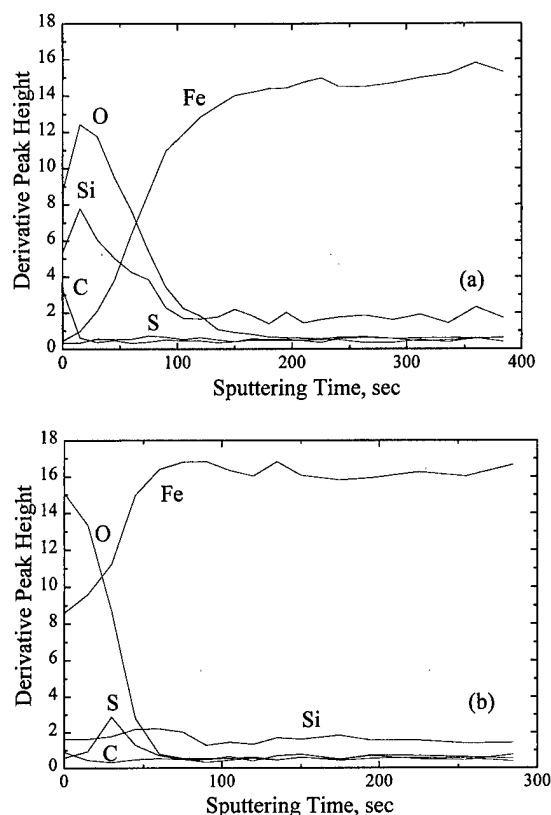

FIG. 5. Ion-sputtering results obtained from the samples finally annealed at 1000 °C: (a) 3.6 and (b) 91.7 ks.

volatile silicon monoxide. As a result, the thickness of the silicon dioxide decreases with final annealing time, and is, as a result, removed on the thin-gauged strip surface. In addition, it is suggested that because the additional silicon segregated on the bare surface without the silicon dioxide also reacts with oxygen¹³⁻¹⁵ in the high vacuum and forms the volatile silicon monoxide, the silicon segregated is not observed on the surface, as shown in Fig. 5(b). On the other hand, the sulfur segregation after the drop of the silicon peak, as shown in Fig. 5(b), can be attributed to a competition between sulfur and silicon in segregation behavior.¹⁶⁻¹⁸

IV. SUMMARY

A correlation between magnetic induction and surface phenomena has been investigated in a 3% Si steel 0.1 mm

thick. During final annealing at 1200 °C, the magnetic induction amounted to 1.98 T after one-step final annealing at 1200 °C for 14.4 ks. This is attributed to the formation of complete (110)[001] Goss texture. The magnetic induction of the thin-gauged 3% Si strip was inversely proportional to the sulfur concentration on the surface. During final annealing at several temperatures, the saturation level in magnetic induction increased with increasing final annealing temperature, and reached 1.93 T after final annealing at 1300 °C for 4.9 ks. However, even after final annealing at 1000 °C for 184.2 ks the saturation level in magnetic induction, 1.71 T, was much lower than that at 1300 °C. During final annealing at 1000 °C, the surface segregation of sulfur occurred after a critical time the silicon concentration on the surface dropped to the level obtained from the α -iron matrix containing 3% Si. The drop in silicon level on the thin-gauged strip surface is due to the volatile silicon monoxide, which arises from the reaction between the silicon dioxide and the silicon segregated, or between the silicon segregated and the oxygen from the high vacuum condition.

New method to predict the magnetic properties of thin gauged Si-Fe sheets

J. G. Na, C. H. Park, J. Kim,^{a)} N. H. Heo,^{b)} S. R. Lee^{c)} C. S. Lee,^{d)} and J. S. Woo^{d)}

Korea Institute of Science and Technology, Seoul 136-791, Korea

A tertiary crystal growth method was used to fabricate thin gauged 3% Si-Fe sheets in order to reduce the thickness of the sheets without deteriorating soft magnetic properties. During the investigation, the magnetic properties of final annealed sheets were found to be directly related to the magnetic properties of final cold rolled sheets. X-ray and transmission electron microscopy were used to understand the above relation. It was found that the fraction of (110) grains at the surface of the final cold rolled sheets significantly affected the final magnetic properties of the final annealed sheets. On the basis of the above argument, the final magnetic properties of the thin gauged Si-Fe sheets can be predicted by the B_{10} values of the final cold rolled sheets. © 1998 American Institute of Physics. [S0021-8979(98)34811-2]

I. INTRODUCTION

Due to excellent soft magnetic characteristics, i.e., low energy losses and high saturation magnetization at low magnetic fields, usually expressed in B_{10} (induced magnetic flux at 10 Oe), grain oriented 3% Si-Fe sheets have been extensively studied and are currently used as core materials of large transformers, large rotating machines, and pole transformers where energy losses during magnetization are of critical concern.^{1,2} The magnetic characteristics of 3% Si-Fe sheets arise from a preferred orientation, i.e., (110)[001] Goss texture formed after cold rolling followed by secondary recrystallization.^{3,4}

It is well known that the energy losses significantly decrease with decreasing thickness of Si-Fe sheets.⁴ Therefore, there have been many investigations to reduce the thickness of the Si-Fe sheets with good (110)[001] texture. After Walter and Dunn,⁵ who reported that a difference in surface energy induced a tertiary recrystallization, thin gauged 3% Si-Fe sheets with good magnetic properties were developed using the tertiary recrystallization in a vacuum.^{6,7}

The production of thin gauged 3% Si-Fe sheets are composed of several procedures including melting and casting, preannealing, 3 times cold-rolling, intermediate annealing, and final annealing, and the magnetic properties of the final annealed sheets are very sensitive to the parameters of each procedure. It is, therefore, very helpful to find a method to predict the final magnetic properties of the thin gauged sheets. During investigating the effect of reduction ratio/pass in the cold rolling processes on the magnetic properties and the microstructures of the sheets, it was found that the final cold rolled sheets that had high B_{10} values showed the high B_{10} values after final annealing. For example, the final cold rolled sheets with B_{10} of 0.83 and 0.76 T exhibited the B_{10}

values of 1.98 and 1.84 T in the final annealed sheets, respectively.

In this paper, the relationship between the magnetic properties of the cold rolled and final annealed sheets was investigated using x-ray and transmission electron microscopy (TEM).

II. EXPERIMENTAL METHODS

100 μm thick 3% Si-Fe sheets were prepared via conventional metallurgical processes including melting and casting, hot rolling to 2.5 mm, preannealing at 800 °C for 30 min, first cold rolling to 0.5 mm, intermediate annealing at 800 °C for 30 min, second cold rolling to 0.25 mm, intermediate annealing at 800 °C for 30 min, final cold rolling to 100 μm and final annealing at 1200 °C for 1 h in a vacuum of 10^{-6} Torr. Detailed processes for the sheets are published elsewhere.⁸

The compositions of the thin 3% Si-Fe sheets, shown in Table I, were analyzed by a chemical method. The microstructures of thin 3% Si-Fe sheets were analyzed by TEM and optical microscope specimens. 10% nital solution was used as an etchant for the optical microscopes. Philips CM-30 was used for TEM analysis and a jet thinning method utilizing 8% perchloric acid + 92% acetic acid was used to perforate TEM specimens. A Seifert XRD-3000PTS was used for x-ray analysis.

The magnetic properties of 3% Si-Fe sheets were measured using a dc flux meter (Toei model TRF-5AH1) and an open circuit method.

III. RESULTS AND DISCUSSION

Figure 1 shows the variations of the B_{10} values of final cold rolled and final annealed thin gauged 3% Si-Fe sheets,

prepared by a tertiary recrystallization method. It shows that the annealed sheets with high B_{10} values also have high B_{10} values in the final cold rolled condition. This simple relationship provides an effective method to predict the final magnetic properties of thin gauged 3% Si-Fe sheets and makes

FIG. 2. (110) pole figure of a final annealed 3% Si-Fe sheet.

possible the avoidance of the high cost final treatment when the sheets will not produce good final properties.

In order to understand the above relationship, the grain orientation and the microstructures of the final cold rolled and the annealed sheets are investigated. Figure 2 shows the $[110]$ pole figure in an annealed sheet, having 1.98 T. It proves that the annealed sheet has excellent $(110)[001]$ texture. Figures 3(a) and 3(b) shows the (110) pole figure of the surface of the cold rolled sheets, which have final B_{10} values of 1.98 T (specimen 1) and 1.84 T (specimen 2), respectively. Both of the specimens have $(111)[112]$ texture but the cold rolled sheet of specimen 1 has more $(110)[001]$ grains compared to the cold rolled sheet of specimen 2. This means that the cold rolled sheet of specimen 1 has a larger area covered with (110) grains than that of specimen 2. Figure 3(c) shows the (110) pole figure of the final cold rolled sheet of specimen 1, obtained in the middle of the specimen by removing top surfaces by chemical etching ($40\text{ }\mu\text{m}$ final thickness). At the center region, the cold rolled sheet of specimen 1 has a $(111)[112]$ texture, which is also found in specimen 2, and a very low fraction of $(110)[001]$ grains compared to the top surfaces.

Figures 4(a) and 4(b) show the TEM images of the cold rolled sheets of specimen 1, which are taken in the middle and top surface, respectively. In Fig. 4(a), a grain is aligned close to the $[111]$ zone axis and the dislocation density is very high. At the center of the cold rolled sheet of specimen 2, the grain orientation and the dislocation density are similar to specimen 1. In Fig. 4(b), there exist two grains; one is aligned close to $[111]$ (representing region A) and the other close to the $[110]$ zone axis (representing region B). It is difficult to quantize the dislocation density of these severely deformed structures because the deformed sheets are relaxed

and continuously change the orientation in their TEM specimens. This makes it too difficult to apply two beam diffraction analyses. In spite of the dislocation density quantization problem, it clearly shows that the dislocation density of region A is much higher than that of region B. In specimen 2, (110) grain was not found due to $(111)[112]$ preferred orientation and (111) grains also have very high dislocation density.

The magnetic easy axis of 3% Si-Fe sheets is located in the $[001]$ direction.⁹ This means that $(110)[001]$ structures could be easily magnetized in the longitudinal direction compared to the $(111)[112]$ structures. There is a significant portion of (110) grains at the surface of the final cold rolled sheet, specimen 1, with high B_{10} as shown in Fig. 3(a). Additionally, the dislocation density of (110) grains at the surface of specimen 1 is quite low as shown in Fig. 4(b). These two factors make specimen 1 have higher magnetization in cold rolled sheets, taking into account that the middle of the sheet with high dislocation density contributes little to B_{10} . Therefore, the (110) grains of the cold rolled sheets are expected to be the dominant factor deciding the magnetization. And the (110) grains also act as seeds for tertiary grain growth. Therefore, specimens having high magnetization values will show high B_{10} values after final annealing. This relation between B_{10} values of the cold rolled and the final annealed sheets gives a critical guideline to predict the magnetic properties after the tertiary recrystallization.

IV. CONCLUSION

Thin gauged 3% Si-Fe sheets show excellent soft magnetic properties after tertiary recrystallization. It was found that high B_{10} values of final cold rolled sheets result in high B_{10} values in final annealed sheets. From pole figure and TEM analyses it was shown that the final cold rolled sheets with high B_{10} had a significant portion of (110) grains having low dislocation density at the surface, while a portion of (110) grains in the cold rolled sheets with low B_{10} was small. At the center of both cold rolled sheets, on the other hand, grains are aligned close to the $[111]$ zone axis and had a very high dislocation density. Thus, the difference in amount of (110) surface grains results in the different magnetic properties of the final cold rolled sheets. These (110) grains are known to be nuclei for a tertiary recrystallization. Therefore, the final magnetic properties of the thin gauged Si-Fe sheets are determined by the portion of (110) grains with low dislocation density. On the basis of the above argument, the final magnetic properties of the thin gauged Si-Fe sheets can be predicted by the B_{10} values of the final cold rolled sheets.

Local distribution on magnetic properties in grain-oriented silicon steel sheet

Masato Enokizono and Ikuo Tanabe

Faculty of Engineering, Oita University, 700 Dannoharu, Oita 870-11, Japan

Takeshi Kubota

Steel Research Laboratories, Nippon Steel Corporation, 20-1 Shintomi, Futaba, Chiba 293, Japan

Grain-oriented silicon steel is the most important soft magnetic material used as core material of large transformers, large rotating machines, and pole transformers. Total loss of grain-oriented silicon steel tends to become lower with an increasing degree of texture. However, the material which has a higher degree of texture ordinarily contains larger grains, and the materials which have larger grains show higher total loss due to increased eddy current loss. As the gauge is reduced, the rate of decrease in total loss becomes lower for the thinner gauge due to increased hysteresis loss. However, the investigation of local magnetic properties due to grain situation in this sheet was not discussed from the viewpoint of the distribution of localized magnetic properties, for example, iron loss, hysteresis loop, behavior H vector (magnetic field strength) and B vector (Magnetic flux density). This paper describes the distribution of magnetic properties in high oriented silicon steel sheet, which are loss, hysteresis loop, and locus of field strength. © 1998 American Institute of Physics. [S0021-8979(98)34911-7]

I. INTRODUCTION

Magnetic properties in electrical steel sheets are usually measured by using the single sheet tester or the Epstein's tester in order to evaluate the materials. In these measurements, the permeability is estimated as a scalar value, that is, the relationship between the magnetic flux density B and the magnetic field intensity H in only the rolling direction. Therefore, the measured property represents an average value in the specimens. However, it is well known that the local distributions of B and H are not uniform in grain-oriented silicon steel sheet. These phenomena are closely related to not only the magnetic properties, but also the local loss distributions. Thus it is necessary to measure the local B and H as vector valuables and to estimate the local iron losses with those vector relations in constructed cores. We have measured the two-dimensional magnetic properties in a grain-oriented sheet by using a small sensor which can be

applied to the local measurement. The result shows the relationship between the magnetic properties and the grain structure in a specimen.

II. MEASURING SYSTEM

Figure 1 shows the measuring apparatus and the measuring points. The specimen used in the experiment was a grain-oriented 3% silicon steel sheet (23 ZH: 100 mm×500 mm×0.23 mm) without insulator coating. The distribution of the grain structure can be observed directly, using the sample sheet without insulator coating. The measuring points were distributed in a 100 mm×100 mm area near the center of specimen and the total number of points were assumed to be 143 as shown in Fig. 1. The points were defined with 13 lines in the rolling direction ($D-P$) and 11 lines in the transverse direction (1-11). The yoke was also constructed with the grain-oriented steel sheet (23 ZH) as shown in Fig. 1. The number of lamination was equal to 7.

FIG. 1. Measuring apparatus.

FIG. 2. Two-dimensional magnetic sensor.

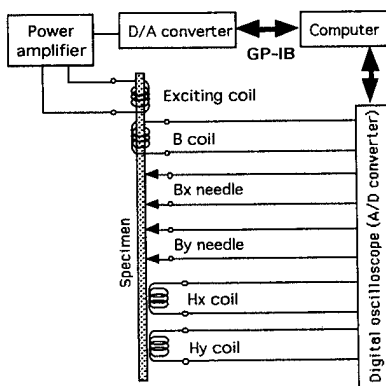

FIG. 3. Measuring system.

FIG. 5. The loci of B vector.

Figure 2 shows the construction of the two-dimensional magnetic sensor.^{1,2} The sensor has two sets of double needles to measure the component of the flux density vector in each direction. The distance between the facing needles was equal to 15 mm. To absorb the vibration of the specimen, a spring was fixed inside the needles. This method, because making a hole array in the specimen is needless, is useful in comparison with the conventional search-coil method. Furthermore, the field changes due to holes are prevented which expands the limit of measuring points. The double H coil was used in measuring the magnetic field intensity vector. The H_x coil was wound around a bakelite plate and the H_y coil was wound over the H_x coil with formal wire 0.04 mm in diameter. The area turns of the H_x coil and H_y coil were 22.5 and 24.5 cm², respectively. Figure 3 shows the measuring system in this experiment. The average flux density in the specimen was controlled to be 1.7 T in sinusoidal waveform by using the output signal from the B coil (1 turn) which was wound at the center of the specimen. The exciting frequencies were 50 and 100 Hz, and the sampling frequencies were 20 and 50 kHz, respectively. The output signals from the sensor were handled with a computer after passing through a digital oscilloscope.

III. RESULTS AND DISCUSSION

Figure 4 shows the relationship between the B vector and H vector at each measuring point at $\omega t = 90$ degrees. As shown in this figure, almost all B vectors were parallel to the rolling direction of the specimen, but most H vectors were not parallel to the B vectors. This phenomenon influences the estimations of iron loss of the grain-oriented silicon steel sheet. It can be observed that the relationships between the B vector and H vector at each measuring position in the same grain were almost similar. Figures 5 and 6 show the loci of the B vector and H vector at each measuring position, respectively. Most loci of the B vectors were alternating, but some of the loci became a slender rotational shape. The loci of the H vectors were quite different from those of the B vectors, and the shapes were dependent on the grain size and its location. Figure 7 shows the loci of the B , H vectors and the hysteresis loop for the X , Y components at some measuring points. Because the measuring area of the sensor at each part was larger than the size of most grains, we could not measure the properties in each grain. However, we can discuss properties at most inner parts of grains or near the boundaries of grains. There were large differences in loci of H vectors at each position. The position D_{-05} was located near the boundary of the neighboring grains and the positions F_{-06} and O_{-07} were almost located in the comparatively

FIG. 4. The relationship between B vector and H vector.FIG. 6. The loci of H vector.

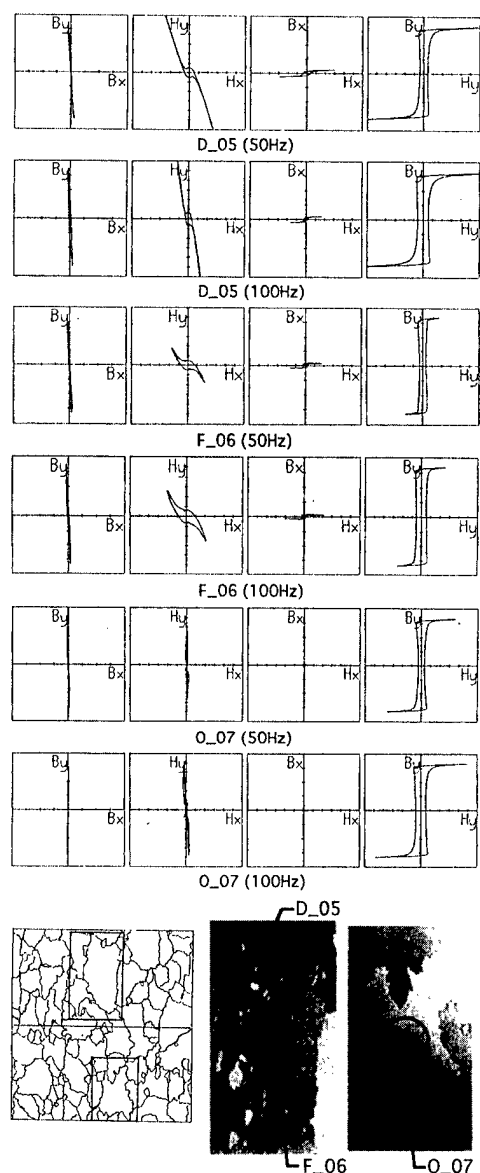

FIG. 7. The loci of the B , H vectors and the hysteresis loop for the X , Y components. The axis of B is 0.5 [T/Div.]. The axis of H is 50 [(A/m)/Div.].

large grains. At D_{-05} and F_{-06} , the loci of H vectors were not parallel to the loci of B vectors, however, the loci of H vectors and B vectors at the O_{-07} position became nearly parallel. One can observe in Figs. 5 and 6 that the H vectors were not locally parallel to the B vectors. This phenomena can be caused by the two following reasons: The demagnetizing field of each grain having different size and shape, influenced each other; there were a few very small grains, which were not consumed after recrystallization, in the large

FIG. 8. The local iron loss distribution. Exciting frequency is 50 [Hz].

grains whose deviation of the $[100]$ direction from the rolling direction was small (F_{-06}). To reduce the iron loss of the silicon steel sheet, it is necessary to remove such small grains that have the $[100]$ direction different from the rolling direction. The changing rate of the loci of H vectors depending on frequency was different at each position. It can be said that those differences in the shape of the hysteresis loops were obviously due to the difference in anisotropy at each grain.

Figure 8 shows the local iron loss distribution in the specimen. The distribution was calculated with the values in both the rolling and transverse direction at each measuring position, and was illustrated with a linear interpolation. The result showed that the loss distributions were not uniform in the sample sheet due to the influence of the grain structure.

IV. CONCLUSION

In this paper, the local iron loss distribution measured by using a two-dimensional magnetic measurement sensor has been presented. The results showed that the distribution of iron loss and the field strength were not uniform in the sample sheet due to the influence of grain structure and its local anisotropy. Because the phenomena widely influence the efficiency of the transformer, the evaluation of such local magnetic properties is very important in improving the characteristics of grain-oriented silicon steel sheet. We intend to clarify the relationship between the local magnetic properties and the domain structure.

Anisotropy design in magnetic media: A micromagnetics study

J. H. Kaufman, T. Koehler,^{a)} A. Moser, D. Weller, and B. Jones

IBM Research Division, Almaden Research Center, 650 Harry Road, San Jose, California 95120-6099

We have investigated the characteristics of model magnetic media using different strategies for the "anisotropy design." We modeled media with intragrain anisotropy oriented random in the plane of the media, random in 3D, and aligned along the track direction, and for a large range of anisotropy field H_k and intergranular exchange J . We report a possible scaling function which collapses data for all three geometries onto a single universal curve. The rescaled data were then analyzed along with the signal-and-noise functions from the various model materials. For any geometry, we find a relation between exchange and anisotropy which maximizes the signal-to-(media) noise function.

© 1998 American Institute of Physics. [S0021-8979(98)33211-9]

I. INTRODUCTION

Magnetic storage media consists of thin hard granular magnetic films.^{1,2} By design these grains are granular and weakly coupled.^{3,4} One can conceive different "designs" of the magnetic anisotropy of these grains. Typically the easy magnetic axis is aligned in the plane of the film by use of appropriate underlayers and deposition temperature. However, one can also allow the easy axis to be random in 3D or perhaps, through underlayer texture, to be oriented in the track direction. It is not clear, *a priori*, which is the best strategy to optimize the overall performance of a recording media. In this work we investigated the effect of anisotropy design on coercivity, and we report a universal scaling function which relates coercivity to exchange, anisotropy, and saturation magnetization, for each of the different geometries.

II. PROCEDURES

The micromagnetics code used in this calculation was written by Koehler and Fredkin.^{5,6} The code uses quasi-static relaxation and a hybrid FEM-BEM method to determine the magnetic state of an arbitrary three dimensional object. The meshing algorithm creates quasi-random tetrahedral elements of the three-dimensional object (film) to be investigated. Each of the tetrahedral elements is treated as an individual "grain." The exchange coupling, J , between grains may be varied along with the remnant magnetization, m_s , and the direction and magnitude of the magnetocrystalline anisotropy field H_k . The calculation was done for a "film" with dimensions $|x| = 1 \mu\text{m}$, $|y| = 2 \mu\text{m}$, $|z| = 200 \text{ \AA}$. This volume was divided into 2878 tetrahedral elements. For each of three anisotropy geometries, the microscopic parameters were varied over a range that produced coercivities and squareness typical of magnetic media. We used $m_s = 500$ (emu/cc), $H_k = 6000, 8000, 10\,000, 12\,000$ (Oe), and

varied the exchange, A , between 1.6×10^{-8} and 4.7×10^{-7} (erg/cm). The input to the model for exchange strength is in terms of the variable J which is dimensionless and model dependent. For a model using a simple cubic mesh, the corresponding constant, J^* , is defined by^{3,4,7}

$$J^* = \frac{2A}{4\pi m_s^2 a^2}, \quad (1)$$

where a is the linear size of the mesh elements in cm. In the Koehler model J also sets an internal scale factor ($l_i = I$) for the computation, and it determines the overall physical length scale (l_p) for the meshed object,

$$J = \frac{2A}{4\pi m_s^2} \left(\frac{l_i^2}{l_p^2} \right) = \frac{2A}{4\pi m_s^2 a^2 (2n^2)} = \frac{1}{(2n^2)} J^*, \quad (2)$$

where $(2n^2)$ is the number of "effective" cubic elements which would fill the $2 \times 1 (\times .02) \mu\text{m}$ slab using a cubic mesh. The number of tetrahedral elements is $5-6 \times$ the number of effective cubic elements.

For each of these "materials," the coercivity was then measured by applying, and switching, an external field in small steps between 10^4 and -10^4 (Oe) in the x direction. The remnant magnetization and coercivities were obtained from the resulting $M-H$ loops.⁸

III. RESULTS AND DISCUSSION

As expected, the coercivity was found to increase with H_k and decrease with increasing A .^{1-4,8,9} The squareness, S^* , increases with A . We looked for a scaling function which would collapse the data (for all values of H_k , A , and for all anisotropy designs) onto a single universal curve. By superposition we expected this function $H_c(J, H_k, \dots)$ to be linear in the anisotropy field and an effective exchange field. The scaling function obtained is shown in Fig. 1. The variables are rescaled by

$$H_c^* = \gamma H_c \quad (3)$$

^{a)}Present address: DAS Devices, 1504 McCarthy Blvd., Milpitas, CA 95035.

FIG. 1. Scaling function for coercivity of granular magnetic media.

and

$$H_k^* = \gamma(H_k - \alpha 4\pi m_s J^*), \quad (4)$$

where we use the more common J^* defined above (J^* differs from J in the Koehler program by a scale factor).

There is only one adjustable parameter, α in this rescaling. The dimensionless variable α represents the number of neighbors which contribute, on average, to the effective exchange field. For the tetrahedral mesh $0 < \alpha < 7$. We find the data collapses onto the scaling function when $\alpha = 4$ for both the random in plane and aligned in plane anisotropy geometries and $\alpha = 6$ for the 3D random anisotropy geometries. Note that in all cases the tetrahedral elements have the same number of geometric neighbors (6–7) and that the same geometric mesh is used in all of the calculations. The other (dimensionless) parameter, γ , in the scaling function is a geometry factor defined by, $\gamma = m_r/m_s$, the ratio between the remnant and saturation magnetization. For each of the geometries, γ may be calculated exactly in the case of weak exchange and large H_k . For the case with anisotropy random in plane,

$$\gamma = \frac{1}{\pi} \int_{-\pi/2}^{\pi/2} d\theta \cos(\theta) = \frac{2}{\pi} = 0.64. \quad (5)$$

For anisotropy distribution random in 3D,

$$\gamma = \frac{1}{2\pi} \int_0^\pi \sin(\theta) d\theta \int_{-\pi/2}^{\pi/2} d\varphi \cos(\varphi) = \frac{1}{2}. \quad (6)$$

A similar analytic expression may be solved for the case with anisotropy aligned in plane using an elliptic distribution of easy axis directions. We created the anisotropy distribution with a ratio of minor to major axes $a/b = 0.2$ and obtained $\gamma = 0.89$. For a perfect orientation of H_k along \hat{X} , $a/b = 0$ and $\gamma = 1$.

For large H_k and small J , the rescaled data asymptotically approaches $H_c^* = H_k^*/3$. Note that the scaling function does not intercept the origin ($H_c^* = H_k^* = 0$). The γ intercept is determined by the shape anisotropy of the finite slab used in the calculation. We measured this separately by performing an $M-H$ loop with low H_c and large exchange and found $H_c^{\text{shape}} \sim 220$ (Oe).

IV. CONCLUSIONS

We found a universal scaling function to relate coercivity to the microscopic parameters m_s , H_k , and J . The function applies in general for all possible designs of anisotropy (random in plane, random in 3D, and aligned in the track direction). In future work we plan to apply this scaling function to the analysis of signal-to-noise data calculated from simulated data tracks using the same parameter space. This holds the promise of providing a recipe to optimize signal to noise as a function of microscopic parameters at any value of coercivity and for arbitrary geometry's of anisotropy.

A variational approach to exchange energy calculations in micromagnetics

M. J. Donahue

National Institute of Standards and Technology, Gaithersburg, Maryland 20899

This article presents a magnetization interpolation method for micromagnetic exchange energy calculations using a variational procedure to relax spins on a supplemental (refined) lattice. The approximations implicit in standard micromagnetic discretization schemes fail when angles between neighboring spins in the model become large, but the proposed approach effectively reduces the angle between neighboring spins, alleviating many of the associated problems. Moreover, this method does not introduce excessive discretization-induced vortex pinning observed with some large angle exchange energy formulations. This article includes details on proper post-interpolation exchange torque calculation, bounds on nearest-neighbor angles for interpolated lattices, a simple model predicting discretization-induced Néel wall collapse, and an example of a collapsed (1 cell wide) domain wall that can be restored by the proposed technique. [S0021-8979(98)33311-3]

I. INTRODUCTION

Many difficulties arise in micromagnetic simulations when angles between neighboring spins become large. Nonetheless, computational limitations often prevent many interesting micromagnetic problems from being discretized at a scale fine enough to resolve all the details of the magnetization structure. In particular, models of thin magnetic films often contain vortices and crossties with unresolved cores measuring only a few nanometers across. As discussed below, such undersampled core regions can collapse during model evolution into one cell wide 180° domain walls, even in settings where the Néel wall width is many cells wide. Once formed, these structures are stable, because they tend to be supported by magnetostatic and crystalline anisotropy fields, and the usual exchange energy formulation provides zero torque across 180° spins. One can introduce an exchange energy formulation modified for large angles, but simple approaches result in strong artificial pinning of vortices to the computation grid.¹

One solution to these problems is to base the exchange energy formulation on a continuous interpolation of the magnetization that respects the constraint that the reduced magnetization $\|m\| = 1$. In this article, an interpolatory "supplemental" lattice is introduced, and a variational procedure is used to relax the spins on this lattice to achieve a smooth interpolation. It is shown that a simple half-step interpolation suffices to avoid the aforementioned one cell wide 180° domain walls, without introducing excessive false pinning of vortices.

II. NÉEL WALL COLLAPSE

Figure 1 shows an example of a situation where an underresolved structure produces errors at a larger scale. This is a simulation of the first μMag standard problem,² a 20 nm thick, $1\ \mu\text{m} \times 2\ \mu\text{m}$ rectangle of $\text{Ni}_{80}\text{Fe}_{20}$ ($M_s = 8.0 \times 10^5\ \text{A/m}$, $A = 1.3 \times 10^{-11}\ \text{J/m}$, $K_u = 500\ \text{J/m}^3$). The weak uniaxial magnetocrystalline anisotropy is directed along the long axis of the film. The computation cells are 25 nm squares, 20 nm thick, with 3D spins. The exchange energy is given by the eight-neighbor dot product formula E_i

$= (A/3) \sum_{n=1}^8 (1 - m_i \cdot m_n)$, detailed in Ref. 1, though similar results are obtained using the more common four-neighbor expression. The magnetostatic fields are calculated via an FFT-based scalar potential method on an offset grid, described in Ref. 3. The magnetization is relaxed using heavily damped Landau-Lifshitz-Gilbert equations of motion. For more details on the calculation technique, see Ref. 4.

The configuration in Fig. 1 is the relaxed state just past the coercive point, after saturation to the left along the long axis of the film. The 180° domain wall in the lower right-hand portion of Fig. 1 was formed in an intermediate (non-relaxed) state as part of a vortex+crosstie pair. The vortex drifted upward (behind the inset, but symmetric with the vortex in the opposite corner), and the crosstie flattened out into the observed 1-cell wide domain wall. It is difficult to predict how wide this wall should be, given the restricted spatial dimensions and the complicated magnetic structure, but one certainly expects it to be wider than a single 25 nm cell.

Figure 2 presents a simple illustrative 1D model of a coarsely discretized Néel wall. (See Refs. 5 and 6 for more on 1D wall models, and Ref. 7 for a numerical study of 2D wall structures.) In this 4 cell model, each cell is a constant magnetization region, infinite along the y axis, with width a

FIG. 1. Simulation results of the μMag first standard problem, using 25 nm square, 20 nm thick calculation cells (4×4 subsample). This is a relaxed state with an applied field of $\mu_0 H = 4.5\ \text{mT}$ directed towards the right. The inset displays all the calculation spins in the dashed box region, showing a collapsed Néel wall.

FIG. 2. Illustration of a simple 1D model to study discretization-induced Néel wall collapse. The outer spins \mathbf{m}_1 and \mathbf{m}_4 are fixed and antiparallel.

as shown, and a thickness t small enough to force the spins to lie in the xy plane. Material parameters are saturation magnetization M_s and exchange constant A . Magnetocrystalline anisotropy is ignored. The outer spins \mathbf{m}_1 and \mathbf{m}_4 are held fixed and antiparallel as shown, while the inner spins \mathbf{m}_2 and \mathbf{m}_3 are allowed to rotate, with θ denoting the angle between the inner spins and their outside neighbor. We make the simplifying assumption that the inner spins are symmetric about the midpoint, as illustrated, because then there are no free poles along the center line, greatly reducing the magnetostatic energy. (This alignment of the center of a Néel wall between discretization nodes is observed in practice.) We also assume that $\theta < 90^\circ$.

Magnetic poles collect along the infinite strip between the two leftmost cells, and between the two rightmost cells. This produces a field at spin \mathbf{m}_2 that acts against the exchange torque produced on \mathbf{m}_2 from \mathbf{m}_3 . If we include the exchange torque at \mathbf{m}_2 from \mathbf{m}_1 , and solve for 0 torque, we find a unique energy minimum at

$$\sec \theta = 2 - \frac{\mu_0 a^2 M_s^2 \{ \arctan(t/a) + \arctan[t/(3a)] \}}{2A\pi},$$

provided the right-hand side is > 1 . Note that as $a \rightarrow 0$, $\theta \rightarrow 60^\circ$ as expected. If the right-hand side is ≤ 1 , then the antiparallel state ($\theta = 0$) is the only stable configuration, and the Néel wall collapses completely. If M_s , A , and t are fixed, then for a sufficiently large the wall will collapse. For a $\text{Ni}_{80}\text{Fe}_{20}$ film with $t = 20$ nm, this works out to a larger than about 7.1 nm, lending credence to the conjecture that a mechanism of this sort is responsible for the wall collapse observed in Fig. 1.

It seems likely that the under-resolved crosstie formed during the evolution to the relaxed state of Fig. 1 produces a local condition not unlike that modeled in Fig. 2, and seeds the collapse of the entire wall. A similar situation can also arise through grid refinement.

Regardless of its origins, the observed Néel wall collapse is made possible by the disappearance of the exchange torque in the antiparallel state. One can try a modified exchange field formulation appropriate for large angles, but simple attempts yield unacceptably strong vortex pinning.¹ More sophisticated interpolations of \mathbf{m} between grid points are made difficult by the apparent importance of the $\|\mathbf{m}\| = 1$ constraint, and the need to produce an interpolation that is consistent across neighboring discretization cells.

A different approach is to interpolate the coarse grid spins $\mathbf{m}_1, \dots, \mathbf{m}_N$ with a differentiable function $\mathbf{m}(x, y, z)$ that minimizes the variational integral

$$E(\mathbf{m}) = A \int (\nabla m_x)^2 + (\nabla m_y)^2 + (\nabla m_z)^2 dV, \quad (1)$$

subject to some constraints. A discrete version of this is developed in the next section. But let us first examine how large an interpolated spin angle can be. As a simple estimate, suppose we are trying to align an interpolating spin $\tilde{\mathbf{m}}$ between neighboring spins $\mathbf{m}_1, \dots, \mathbf{m}_n$. Consider all of these spins as points in S^2 , the unit sphere in \mathbf{R}^3 . If the angle between $\tilde{\mathbf{m}}$ and spin \mathbf{m}_i is to be less than θ , then $\tilde{\mathbf{m}}$ must lie outside the circular disk symmetrically opposite to \mathbf{m}_i on S^2 with diameter $2\pi - 2\theta$. The area of such a disk is $2\pi(1 + \cos \theta)$. This is true for each i , so if the total area of n such disks is less than the total area of the sphere, then there exists a $\tilde{\mathbf{m}}$ that is no farther than θ from each of the spins $\mathbf{m}_1, \dots, \mathbf{m}_n$. Solving for θ we find $\theta \leq \arccos(-1 + 2/n)$. As an example, if we are trying to fit $\tilde{\mathbf{m}}$ between four fixed spins, then there is a direction for $\tilde{\mathbf{m}}$ that is at most $\arccos(-1 + 2/4) = 120^\circ$ from each of the fixed spins.

III. THEORY

We now develop a discrete analog to (1). Given the coarse grid spins $\mathbf{m} = (\mathbf{m}_1, \dots, \mathbf{m}_N)$, we want to find interpolating spins $\tilde{\mathbf{m}} = (\tilde{\mathbf{m}}_1, \dots, \tilde{\mathbf{m}}_K)$ solving

$$\min_{\tilde{\mathbf{m}}} F(\mathbf{m}; \tilde{\mathbf{m}}) \quad \text{subject to} \quad \Phi(\tilde{\mathbf{m}}) = \mathbf{0}, \quad (2)$$

where $\Phi = (\phi_k)$ is a collection of constraints, $k = 1, \dots, K$. (In Sec. IV we will use $\phi_k(\tilde{\mathbf{m}}) = \|\tilde{\mathbf{m}}_k\| - 1$.) We will assume that both the objective function F and the constraints are differentiable.

Let us assume for the moment that the interpolated spins $\tilde{\mathbf{m}}$ are differentiable with respect to \mathbf{m} , and use the extended discretization set $(\mathbf{m}, \tilde{\mathbf{m}})$ to evaluate the exchange energy $E(\mathbf{m}) = \tilde{E}[\mathbf{m}, \tilde{\mathbf{m}}(\mathbf{m})]$.

To relax our solution over \mathbf{m} , whether by integrating the Landau-Lifshitz-Gilbert equations, or through direct energy minimization, we needed to know $\partial E / \partial \mathbf{m}$:

$$\frac{\partial E}{\partial \mathbf{m}_i} = \frac{\partial \tilde{E}}{\partial \mathbf{m}_i} + \sum_{j=1}^N \frac{\partial \tilde{E}}{\partial \tilde{\mathbf{m}}_j} \frac{\partial \tilde{\mathbf{m}}_j}{\partial \mathbf{m}_i}. \quad (3)$$

We have only an implicit relation for $\tilde{\mathbf{m}}$ in terms of \mathbf{m} , so the last term above is difficult to evaluate. However, suppose we use \tilde{E} as the objective function F in (2). It follows from the theory of Lagrange multipliers that if $(\partial \phi_k / \partial \tilde{\mathbf{m}}_j)_{k,j}$ has full rank $K < \tilde{N}$, then at a local minimum $\tilde{\mathbf{m}}$ we can write $\partial \tilde{E} / \partial \tilde{\mathbf{m}}$ as a linear combination of $\partial \phi_k / \partial \tilde{\mathbf{m}}$ i.e.,

$$\frac{\partial E}{\partial \mathbf{m}_i} = \frac{\partial \tilde{E}}{\partial \mathbf{m}_i} + \sum_{k=1}^K \lambda_k \sum_{j=1}^{\tilde{N}} \frac{\partial \phi_k}{\partial \tilde{\mathbf{m}}_j} \frac{\partial \tilde{\mathbf{m}}_j}{\partial \mathbf{m}_i}.$$

If the constraints Φ are independent of \mathbf{m} , then the last sum is zero, and we get the simple relation

$$\frac{\partial E(\mathbf{m})}{\partial \mathbf{m}} = \frac{\partial \tilde{H}[\mathbf{m}, \tilde{\mathbf{m}}(\mathbf{m})]}{\partial \mathbf{m}}.$$

The one difficulty is that we cannot guarantee the differentiability of $\tilde{\mathbf{m}}$ with respect to \mathbf{m} . More work needs to be done to identify and handle those spin configurations for which differentiability is lost, but in practice such occurrences appear to be relatively uncommon.

IV. RESULTS AND CONCLUSIONS

To test this interpolation technique, we introduced a supplemental lattice to the simulation described in Sec. II. The supplemental lattice interpolated the main grid at half the cell dimension, i.e., with 12.5 nm square cells. The eight-neighbor dot product exchange energy formulation was minimized to determine the spins on the supplemental lattice (holding fixed the spins on the original lattice), subject to the constraint $\|\mathbf{m}\|=1$ for all spins. (For this initial study, we employed a simple gradient descent minimization algorithm, which required computation time comparable to that of the demagnetization calculation. We expect a sophisticated minimization algorithm will be much faster.) The refined lattice is used only for the exchange energy and exchange torque calculations.

The magnetization configuration in Fig. 1 is not a stable state under the new scheme, but using it as an initial state and allowing the simulation to evolve to a new energy minimum yields Fig. 3. Note that the interpolation has allowed the crosstie to reform, and the domain wall is now a resolved Néel wall. These results are similar to those obtained using the standard exchange scheme and a “real” refinement with 12.5 nm cells. Conversely, using the proposed method the Néel wall does not collapse even with 50 nm cells (and a 25 nm supplemental lattice).

As another test, we repeated the vortex pinning simulations detailed in Ref. 1, and found no increase in the vortex pinning field.

FIG. 3. Simulation results using the described interpolation technique, with Fig. 1 as the initial state ($\mu_0 H = 4.5$ mT). The collapsed wall in that figure has expanded into a crosstie and a resolved Néel wall.

It is important to distinguish this interpolation technique from a straightforward grid refinement. In the proposed technique the interpolated spins affect only the exchange energy, and at each step the interpolated spins are relaxed completely to an exchange energy minimum (holding fixed the spins on the coarse mesh). Because of this, the angle between neighboring spins on the refined mesh cannot collapse to 180° , as described in Sec. II. Instead, this technique effectively produces an exchange energy formulation that does not break down in the case of large angles between neighboring spins, yet does not increase vortex pinning.

Experiments on ferromagnetic thin films have measured the dependence of the hysteresis loop area on the amplitude and frequency of the external field, $A=A(H_0, \omega)$, and approximate agreement with numerical simulations of Ising models has been reported. Here we present numerical and theoretical calculations of A in the low-frequency regime for two values of H_0 , which bracket a temperature and system-size dependent crossover field. Our previous Monte Carlo studies have shown that the hysteretic response of the kinetic Ising model is qualitatively different for amplitudes above and below this crossover field. Using droplet theory, we derive analytic expressions for the low-frequency asymptotic behavior of the hysteresis loop area. In both field regimes, the loop area exhibits an extremely slow approach to an asymptotic, logarithmic frequency dependence of the form $A \propto -[\ln(H_0\omega)]^{-1}$. Our results are relevant to the interpretation of data from experiments and simulations, on the basis of which power-law exponents for the hysteresis-loop area have been reported. © 1998 American Institute of Physics. [S0021-8979(98)23811-4]

When a ferromagnet is subject to an oscillating external field, $H(t)=H_0 \sin \omega t$, the time-dependent magnetization, $m(t)$, typically lags behind the field. The area of the resulting hysteresis loop, $A=-\oint m(H)dH$, equals the energy dissipated per period. It is therefore frequently measured in studies of periodically driven magnetic systems. Recent experiments on ultrathin ferromagnetic films,^{1,2} as well as numerical simulations of two-dimensional Ising models,³⁻⁶ have been interpreted in terms of a low-frequency power law, $A \propto H_0^a \omega^b$, with a range of exponent values having been reported.⁴⁻⁶ This interpretation is not fully consistent with the fluctuation-free mean-field result,^{7,8} $A=A_0 + \text{const}[\omega^2(H_0^2 - H_{sp}^2)]^{1/3}$ with positive constants A_0 and H_{sp} , which has been successfully applied to analyze experiments on ultrathin films of Co on Cu(001).⁹ Nor does the single power-law dependence agree with the logarithmic dependence expected if thermally activated nucleation is the rate-determining process.¹⁰⁻¹² Here we present analytical and numerical results that indicate a resolution of this puzzling situation.

Theoretical arguments and numerical simulations reveal parameter regimes in which, following instantaneous field reversal, a uniaxial single-domain ferromagnet switches to the stable magnetization direction via two distinct mechanisms. This magnetization reversal occurs either by nucleation of a *single* critical droplet of the stable phase [the single-droplet (SD) regime] or by simultaneous nucleation and growth of *many* critical droplets [the multi-droplet (MD) regime].¹²⁻¹⁴ The SD (MD) regime corresponds to weaker (stronger) fields and/or smaller (larger) systems. In this extension of our previous studies of hysteresis,¹⁵ we present

analytical and Monte Carlo results for the hysteresis-loop area for a kinetic Ising model at low frequencies; both in the SD regime and in the MD regime. The derivations are based on time-dependent extensions of classical homogeneous nucleation theory and “Avrami’s law” for the decay of a metastable phase.¹⁶ For both decay mechanisms, we show how an extremely slow approach of A to an asymptotic logarithmic dependence on $H_0\omega$ as $\omega \rightarrow 0$ gives “effective exponents” which superficially appear to describe a power law, even for data extending over several decades in frequency.

The model used here is a kinetic, nearest-neighbor Ising ferromagnet on a square lattice with Hamiltonian $\mathcal{H} = -J \sum_{\langle ij \rangle} s_i s_j - H(t) \sum_i s_i$ and periodic boundary conditions. Here $s_i = \pm 1$ are the local spin variables, $\sum_{\langle ij \rangle}$ runs over all nearest-neighbor pairs, and \sum_i runs over all $N=L^2$ lattice sites. The ferromagnetic exchange coupling is $J>0$, and $H(t)$ is a time-dependent external field. The dynamic is the Glauber single-spin-flip algorithm, with updates at randomly chosen sites. It is defined by the spin-flip probability $W(s_i \rightarrow -s_i) = \exp(-\beta \Delta E_i) / (1 + \exp(-\beta \Delta E_i))$, where ΔE_i is the change in the energy of the system if the spin flip is accepted, and $\beta^{-1} = k_B T$ is the temperature in energy units. Time is given in units of Monte Carlo steps per spin (MCSS). The average lifetime, $\langle \tau(|H|) \rangle$, of the unfavorably magnetized phase in a *static* field of magnitude $|H|$ is defined as the average time it takes the magnetization to reach zero, following instantaneous field reversal. The frequency, ω , of the applied sinusoidal field, is chosen by specifying the ratio $R = (2\pi/\omega) / \langle \tau(H_0) \rangle$.

^{a)}Electronic mail: sides@scri.fsu.edu

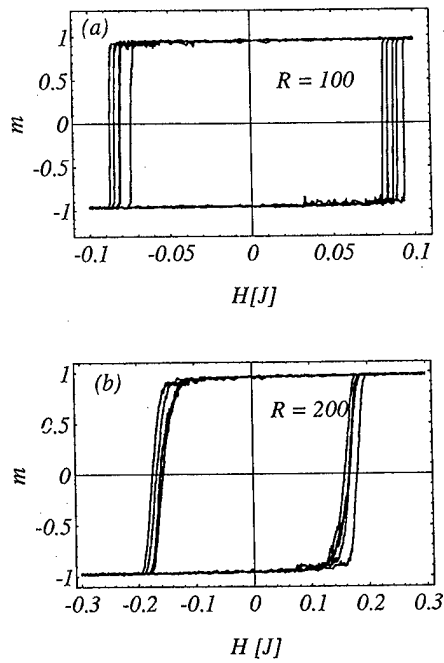

FIG. 1. Low-frequency hysteresis loops from simulations of a kinetic Ising model. For both regimes five loops are shown, representing short portions of the entire simulation time series. (a) Loops from the single-droplet (SD) regime, using $H_0 = 0.1$ J at a scaled frequency of $1/R = 0.01$. (b) Loops from the multi-droplet (MD) regime, using $H_0 = 0.3$ J at a scaled frequency of $1/R = 0.005$.

We initially prepare a system of size $L = 64$ at $T = 0.8T_c$ with all spins down, i.e., $m(0) = -1$. Then the sinusoidal field $H(t) = H_0 \sin \omega t$ is applied, and $m(t)$ is recorded for a fixed number of MCSS, n_{\max} . For the simulations in the SD regime, the field amplitude is $H_0 = 0.1$ J (which gives $\langle \tau \rangle = 2058$ MCSS) with $n_{\max} = 16.9 \times 10^6$ MCSS. For the MD regime, the amplitude is $H_0 = 0.3$ J (which gives $\langle \tau \rangle = 75$ MCSS) with $n_{\max} = 5.9 \times 10^5$ MCSS. For the values of L and T used here, the crossover field [called the Dynamic Spinodal¹⁴ (DSP)] between these two regimes is $H_{\text{DSP}} \approx 0.11$ J. For large systems H_{DSP} vanishes slowly with L as $H_{\text{DSP}}(L) \sim (\ln L)^{-1/(d-1)}$. Figure 1 shows representative hysteresis loops from simulations in both the SD and MD regimes. The large relative fluctuations in the loop area in Fig. 1(a) indicate the stochastic nature of the switching mechanism in the SD regime.¹⁷ The relative fluctuations in the loop area are smaller in the MD regime [Fig. 1(b)]. The stochastic nature of magnetization reversal in the SD regime allows one to treat the switching as a variable-rate Poisson process. For low frequencies, this variable switching rate is the system volume times the nucleation rate obtained from classical droplet theory,

$$L^d I(H(t), T) \propto L^d |H(t)|^K \exp \left[-\frac{\Xi_0(T)}{|H(t)|^{d-1}} \right], \quad (1)$$

where d is the spatial dimension of the system, and K and $\Xi_0(T)$ are known from theory and simulations.^{13,14} The quantity $\Xi_0(T)$ is the field-independent part of the free-energy cost of a critical droplet, divided by $k_B T$. The time dependence of the nucleation rate enters solely through $H(t)$. Using Eq. (1) one can derive an expression for the cumula-

FIG. 2. Log-log plot of $\langle A \rangle / 4H_0$ vs $1/R$ in the SD regime. The solid curve is obtained from the numerical solution of Eq. (2), the derivation of which is outlined in the text. The dashed line segments represent linear least-squares fits to different portions of the numerical solution data. The data that yield the effective exponent $b = 0.096$, are centered around $\log(1/R) = -2.05$; those that yield $b = 0.033$ are centered around $\log(1/R) = -13.38$. The two solid dots are MC simulation data. The vertical lines are not error bars; they represent the standard deviation of the loop-area distribution.

tive probability that a switch has taken place by time t , $F(t)$.¹⁷ The median switching time, t_s , is given by $F(t_s) = 1/2$. To obtain an analytic result we use the low-frequency approximation $H(t) \approx H_0 \omega t$. Then the median switching field, $H_s = H_0 \omega t_s$, is given by the solution of the equation,

$$\ln 2 = \rho_0 \frac{e^{\frac{\Xi_0(T)}{H_0^{d-1}} \frac{K+1}{d-1}}}{H_0^{K+1} (d-1) \omega} \times \Gamma \left(1 - \frac{K+d}{d-1}, \frac{\Xi_0}{H_s^{d-1}} \right), \quad (2)$$

where $\Gamma(a, x)$ is the incomplete gamma function, and ρ_0 is the switching rate in a static field of magnitude H_0 , which has been measured in field-reversal simulations.¹⁷

Due to the square shape of the hysteresis loop in both regimes, the loop area is given by $\langle A \rangle / 4H_0 \approx m_{\text{eq}} H_s(\omega) / H_0$, where m_{eq} is the spontaneous zero-field magnetization. Figure 2 is a log-log plot of the hysteresis-loop area versus the frequency, $1/R$, in the SD regime. The solid curve is calculated by numerical solution of Eq. (2) with $d=2$, $K=3$, $\Xi_0 = 0.506192$ J, and $\rho_0 = 6.62 \times 10^{-4}$ MCSS⁻¹. Hence, this calculation involves no adjustable parameters. The solid dots are data from MC simulations. Each of the two dashed lines is obtained from a linear least-squares fit to the numerical solution for the loop area over nearly four decades in frequency. The effective exponents obtained from this fitting procedure appear valid over a frequency range that would be considered large from the viewpoint of experiments or even simulations. Over a very large frequency range however, the effective exponent depends on the frequency range in which data are analyzed. Expanding $\Gamma(a, x)$ in Eq. (2) for large values of $x = \Xi_0 / H_s^{d-1}$ gives the asymptotic low-frequency result $\langle A \rangle_{\text{SD}} \propto [\ln(H_0 \omega)]^{-1/(d-1)}$.

The details of the theoretical derivation of the loop area in the MD regime are different than in the SD regime. However, two basic features are the same: the form of the time-dependent nucleation rate, $I(H(t), T)$ from Eq. (1), and the linear approximation for the field used to obtain asymptotic

FIG. 3. Log-log plot of $\langle A \rangle / 4H_0$ vs $1/R$ in the MD regime. The solid curve is obtained from a full numerical integration of the time-dependent Avrami's law result for $m(t)$, using a sinusoidal field, $H(t) = H_0 \sin \omega t$. (This calculation could not be extended to lower frequencies than those shown due to numerical difficulties.) The dotted curve is obtained from a numerical solution of an analytic expression whose derivation uses a linear approximation for the field, $H(t) \approx H_0 \omega t$. The solid dots represent MC simulations. The vertical bars denote the standard deviation in the loop-area distributions as in Fig. 2. The dashed curve represents the SD result (the solid curve in Fig. 2) after rescaling so that the SD and MD results may be compared.

analytic results for very low frequencies. Figure 3 is a log-log plot of the hysteresis-loop area versus $1/R$ in the MD regime. The solid curve results from a full numerical integration (NI) of an analytic expression for $m(t)$, obtained from Avrami's law,¹⁶ with the sinusoidal form of $H(t)$. The dotted curve results from a numerical solution (NS) of an analytic expression obtained from a linear approximation for $H(t)$, as for the SD regime. The transcendental equation that must be solved is analogous to Eq. (2), but contains a sum of three incomplete gamma functions.¹⁷ The MC data (solid dots), NI and NS results are in excellent agreement. For $d=2$ and *extremely* low frequencies, an asymptotic expansion of the analytic expression used to obtain the NS result gives $\langle A \rangle_{\text{MD}} \propto -[\ln(H_0 \omega)]^{-1}$. As in the SD case, from a log-log plot of the loop area versus frequency one can extract effective exponents from the data over nearly two decades in $1/R$. However, these effective exponents depend strongly on the frequency range in which the fit is performed. Similarly, if A is plotted vs $-\ln(H_0 \omega)$ as in Ref. 10, the slow crossover will result in a significant overestimate of the asymptotic exponent $1/(d-1)$.

A change from MD to SD behavior should appear not only as $H_0 \rightarrow H_{\text{DSP}}$, but for finite systems it should be observed when ω becomes sufficiently low that $H_s < H_{\text{DSP}}(L)$. The frequency of this crossover should be given by the intersection of the results for the loop areas in the SD and MD regions. The dashed curve in Fig. 3 represents the solid curve in Fig. 2, which has been rescaled so that the two results may be plotted together. The value of the loop area at the intersection is that of a loop with $H_s \approx H_{\text{DSP}}(L)$. While $m(t)$ and A do not depend on system size in the MD regime, A in the

SD region, and hence the location of the crossover, depends on L .

In conclusion, we have shown that the hysteresis-loop areas for kinetic Ising ferromagnets driven by oscillating external fields vanish logarithmically with $H_0 \omega$ for asymptotically low frequencies. This result should be valid for all fields and temperatures such that magnetization switching proceeds via a homogeneous nucleation-and-growth mechanism,^{10,11} in particular for both the single-droplet and multidroplet regimes considered here. For both of these regimes we stress that the asymptotic low-frequency behavior would only be seen for *extremely* low frequencies. For frequencies in a more "realistic" range, we find a wide crossover, extending over many decades in frequency. Power law fits to the loop areas over as much as four frequency decades give good agreement within the fitting range, but the resulting effective exponents depend strongly on the fitting interval. We believe our results are significant to the interpretation and comparison of results from experimental^{1,2,9} and numerical⁴⁻⁶ studies of hysteresis in ferromagnetic systems, in which power-law dependences of the loop areas have been reported with a variety of exponents.

Two different approaches to hysteresis modeling are compared using a common ground based on energy relations, defined in terms of dissipated and stored energy. Using the Preisach model and assuming that magnetization is mainly due to domain-wall motion, one can derive the expression of magnetization along a major loop typical of the Jiles–Atherton model and then extend its validity to cases where mean-field effects and reversible contributions are present. © 1998 American Institute of Physics. I. INTRODUCTION

The Preisach¹ and Jiles–Atherton² models are two widely used approaches to the description of magnetic hysteresis. They have been applied to a wide range of static and dynamic conditions, ranging from the solution of circuits containing hysteretic components to microstructural analysis.^{3–5} Their physical significance can be best appreciated when modeling features are reduced to fundamental energetic aspects, and this result is particularly helpful in the clarification of the relations between different approaches to hysteresis modeling. In this paper, we show that by referring to fundamental energy relations, which can be used to describe the models in terms of stored and dissipated energy, one is able to derive the fundamental expression of magnetization laws of the Jiles–Atherton model by applying a physically meaningful set of assumptions to the Preisach model.

When work is performed by external sources on a system displaying hysteresis, part of the energy is stored and part is dissipated. This energy balance can be described using a model which takes into account a minimum set of relevant physical quantities. Considering, for example, a homogeneous magnetic system and assuming, for the sake of simplicity, that the bulk magnetization M is aligned to the applied magnetic-field H_α , the general expression for the balance between stored and dissipated energy can be expressed as

$$-\mu_0 M dH_\alpha = dg + \delta Q, \quad (1)$$

where dg corresponds to the change in free energy per unit volume and δQ is the dissipated energy term. In this paper, we show how one can express the terms of Eq. (1) with quantities easily recognized in each of the modeling schemes, and furthermore, how this can be used as a common reference for the quantitative comparison of the Jiles–Atherton and Preisach models.

^{a)}Electronic mail: pasquale@ien.it

II. JILES–ATHERTON MODEL

In the case of the Jiles–Atherton model, it is assumed that the free-energy term dg of Eq. (1) can be expressed in terms of the anhysteretic curve $M_{an}(H_\alpha)$; the idea is that the energy supplied coincides with the change in magnetostatic energy in the absence of hysteresis:

$$dg = -\mu_0 M_{an} dH_\alpha. \quad (2)$$

The other term of Eq. (1), δQ , corresponding to the dissipated energy, will be the difference between the energy supplied and the change in magnetostatic energy. This can be taken to be proportional to the change in magnetization,

$$\delta Q = \mu_0 k dM, \quad (3)$$

since dM can be thought to be proportional to the number of pinning sites seen by a moving domain wall; and each pinning event giving rise to Barkhausen jump, when integrated over the entire specimen, will produce a dissipation contribution proportional to the pinning site density k . The dissipation is always positive, that is, there can be loss of energy only, and therefore, in Eq. (3) and the subsequent analysis it is implicitly assumed that dM is positive. The equations can easily be modified to take into account a negative dM . Using these assumptions, Eq. (1) becomes then,

$$-\mu_0 M dH_\alpha = -\mu_0 M_{an} dH_\alpha + \mu_0 k dM, \quad (4)$$

which can be directly written as

$$\frac{dM}{dH_\alpha} = \frac{M_{an}(H_\alpha) - M(H_\alpha)}{k}, \quad (5)$$

which is the simplest expression of the basic magnetization law of the Jiles–Atherton model² in the absence of an internal coupling field.

III. PREISACH MODEL

In the Preisach model, hysteresis is described starting from the hypothesis that a free-energy profile characterized by multiple local minima and metastable states can be decomposed into a set of many elementary bistable contributions. Each bistable unit can occupy one of two states, which we shall call (+) and (−) states and is characterized by two

fields h_c and h_u , respectively proportional to the height of the barrier separating the (+) and (−) states and to the energy difference of the (+) and (−) states. The basic relation of the magnetization in the Preisach model is

$$M = 2M_s \int_0^\infty dh_c \int_0^{b(h_c)} dh_u p(h_c, h_u), \quad (6)$$

obtained by integration on the plane defined by the ensemble of bistable units. The integration upper limit $b(h_c)$ consists of a chain of segments of alternating slope $db/dh_c = +1$ and $db/dh_c = -1$ generated by the past field history. This line defines the partition of the Preisach plane in only one (+) and one (−) region.¹ In the case of the saturation loop branch with peak-field H_α , $b(h_c)$ becomes simply $H_\alpha - h_c$, a segment of slope $db/dh_c = -1$. The physical meaning of the Preisach model emerges clearly when one considers the properties of domain walls (DW) moving in this complex energy profile, which is rich in metastable states. It has been proved⁶ that the hysteresis properties of a DW moving in a Wiener-like pinning field profile can be described by the Preisach hysteresis model, where the Preisach distribution $p(h_c, h_u)$, weighting the elementary contributions, is proportional to

$$p(h_c, h_u) \propto \exp(-h_c/k), \quad (7)$$

independent of h_u where k describes the statistical properties of the pinning field. This result pertains to indefinite wall motion and contains no description of magnetic saturation. Saturation can then be taken into account by modifying Eq. (7) into

$$p(h_c, h_u) \propto u(h_c) \nu(h_u), \quad (8)$$

where the ν function is an integrable even function of h_u . This generalization corresponds again to the physical picture where stored energy (represented by the h_u variable) and dissipated energy (represented by h_c) can be factorized as $u(h_c) \nu(h_u)$ for a proper description of the system.

In the case of a saturation loop branch, by applying Eq. (8) to Eq. (6) for the calculation of the saturation loop branch, one will obtain a relation identical to the Jiles–Atherton hysteresis model² where the integral of $\nu(h_u)$ coincides with the anhysteretic curve. This curve represents the nondissipation limit of the magnetization process, and it can be obtained for any value of applied-field H_α by applying an oscillating field history with decreasing peak amplitude in order to demagnetize the material in the bias field H_α . The anhysteretic curve is closely connected with the function $\nu(h_u)$. In fact, the upper integration limit $b(h_c)$ associated with the anhysteretic state assumes the particularly simple form $b(h_c) = H_\alpha$ when the demagnetization is performed using an arbitrarily large number of decreasing steps.¹ In this case, Eq. (8) can be written as

$$M_{an}(H_\alpha) = 2M_s \int_0^\infty dh_c \int_0^{H_\alpha} dh_u u(h_c) \nu(h_u), \quad (9)$$

and if the dissipation term is normalized so that

$$\int_0^\infty dh_c u(h_c) = 1, \quad (10)$$

the anhysteretic magnetization can simply be expressed as

$$M_{an}(H_\alpha) = 2M_s \int_0^{H_\alpha} dh_u \nu(h_u), \quad (11)$$

and $\nu(h_u)$ must, therefore, be the derivative of M_{an} with respect to h_u rescaled by some constant. This result follows directly from the chosen factorization Eq. (7) of the Preisach distribution. Considering now the expression for magnetization of Eq. (6), one obtains an expression for dM ,

$$\frac{dM}{dH_\alpha} = 2M_s \int_0^\infty \frac{dh_c}{k} \exp(-h_c/k) \nu(H_\alpha - h_c), \quad (12)$$

that integrated by parts gives

$$\frac{dM}{dH_\alpha} = \frac{1}{k} [M_{an}(H_\alpha) - M(H_\alpha)], \quad (13)$$

which demonstrates the actual equivalence between the Preisach and Jiles–Atherton models in the calculation of a saturation branch, under the hypothesis of DW dominance and saturation approach according to an anhysteretic law. The result in Eq. (13) can be used to clarify the equivalence through the direct comparison of the terms appearing in Eq. (1) derived from the two models, and to this end we will write Eq. (13) for later use as

$$\mu_0 k dM = \mu_0 M_{an} dH_\alpha - \mu_0 M dH_\alpha. \quad (14)$$

It has also been shown in Ref. 7 that through the Preisach operator of Eq. (6) one can obtain an expression for the terms δQ and g appearing in Eq. (1):

$$\delta Q = \left| 2\mu_0 M_s \int_0^\infty dh_c h_c p[h_c, b(h_c)] \delta b(h_c) \right|, \quad (15)$$

and

$$g = 2\mu_0 M_s \int_0^\infty dh_c \int_0^{b(h_c)} dh_u (h_u - H_\alpha) p(h_c, h_u), \quad (16)$$

where $\delta b(h_c)$ represents a small variation of the integration limit, i.e., a small variation of the state of the system consequent to a small field variation dH_α . Now, if δQ is written using Eqs. (7) and (8) and then it is integrated by parts, one obtains

$$\begin{aligned} \delta Q = & 2\mu_0 M_s \int_0^\infty dh_c \exp(-h_c/k) \nu(H_\alpha - h_c) dH_\alpha \\ & - 2\mu_0 M_s \int_0^\infty dh_c h_c \exp(-h_c/k) \\ & \times \left[\frac{d\nu(x)}{dx} \right]_{x=H_\alpha-h_c} dH_\alpha, \end{aligned}$$

where substituting

$$\begin{aligned} \mu_0 X dH_\alpha = & 2\mu_0 M_s \int_0^\infty dh_c h_c \exp(-h_c/k) \\ & \times \left[\frac{d\nu(x)}{dx} \right]_{x=H_\alpha-h_c} dH_\alpha, \end{aligned}$$

one will be able to write

$$\delta Q = \mu_0 H_0 dM - \mu_0 X dH_\alpha. \quad (17)$$

Finally, Eqs. (14) and (17) can be combined with Eq. (1) to obtain an expression of dg :

$$dg = -\mu_0 M_{\text{an}} dH_\alpha + \mu_0 X dH_\alpha, \quad (18)$$

and this result, when compared with Eqs. (2) and (3) shows that both the Preisach and Jiles–Atherton models are fully consistent with the energy balance expressed in Eq. (1), even though a deviation term is observed.

A. Irreversible and reversible magnetization

In Eq. (13) it has been shown that the expressions for magnetization derived in the Preisach framework can be used to obtain an expression for magnetization along the major loop as in the Jiles–Atherton model. The general expression for total magnetization M is usually given as the sum of two contributions M_{irr} and M_{rev} . Equations (6) and (8) refer to the irreversible part only, so that

$$M_{\text{irr}}(H_\alpha) = \frac{2M_s}{k} \int_0^\infty dh_c \int_0^{H_\alpha - h_c} dh_u \exp(-h_c/k) \nu(h_u), \quad (19)$$

and the Jiles–Atherton relation (5) becomes

$$\frac{dM_{\text{irr}}(H_\alpha)}{dH_\alpha} = \frac{1}{k} [M_{\text{an}}(H_\alpha) - M_{\text{irr}}(H_\alpha)]. \quad (20)$$

Reversible magnetization processes can be quite naturally introduced in the Preisach model by association with elementary hysteresis loops with no energy dissipation, e.g., where $h_c = 0$. These objects will be distributed along the h_u axis and they can be defined using Dirac's delta function $\delta(h_c)$. The Preisach distribution referring to total magnetization is then the sum of two parts, both multiplied by the same function $\nu(h_u)$,

$$[(1-c)u(h_c) + c\delta(h_c)]\nu(h_u), \quad (21)$$

where $\delta(h_c)$ is the Dirac function.

Using Eq. (21) and referring to the general expression for magnetization in Eq. (6) and (9), where one can substitute $p(h_c)$ with $\delta(h_c)$, the reversible contribution to magnetization can be written as

$$\begin{aligned} M_{\text{rev}}(H_\alpha) &= c2M_s \int_0^\infty dh_c \int_0^{H_\alpha} dh_u \delta(h_c) \nu(h_u) \\ &= cM_{\text{an}}(H_\alpha), \end{aligned} \quad (22)$$

having made use of Eq. (13). With this result, total magnetization can be written both for the Preisach and the Jiles–Atherton models as

$$dM = [(1-c)dM_{\text{irr}} + cdM_{\text{an}}]. \quad (23)$$

B. Mean-field contributions

Wishing to express the same quantities in the presence of a mean-field interaction, one has to distinguish the applied-field H_α from the internal-field H_{eff} , which is equal to the sum of the applied field and a coupling term proportional to magnetization through a coefficient $\alpha \neq 0$:

$$H_{\text{eff}} = H_\alpha + \alpha M, \quad (24)$$

taking the derivative of H_α with respect to internal-field H_{eff} one obtains,

$$\frac{dH_\alpha}{dH_{\text{eff}}} = 1 - \alpha \frac{dM}{dH_{\text{eff}}}, \quad (25)$$

which can be used to write the derivative of M with respect to H_α ,

$$\frac{dM}{dH_\alpha} = \frac{dM}{dH_{\text{eff}}} \bigg/ \frac{dH_\alpha}{dH_{\text{eff}}} = \frac{dM}{dH_{\text{eff}}} \bigg/ \left(1 - \alpha \frac{dM}{dH_{\text{eff}}} \right). \quad (26)$$

Now one is able to write Eq. (20) using H_{eff} instead of H_α ,

$$\frac{dM(H_{\text{eff}})}{dH_{\text{eff}}} = \frac{1}{k} [M_{\text{an}}(H_{\text{eff}}) - M_{\text{irr}}(H_{\text{eff}})],$$

and transform it to a derivative with respect to H_α :

$$\frac{dM(H_\alpha)}{dH_\alpha} = \frac{M_{\text{an}}(H_\alpha) - M_{\text{irr}}(H_\alpha)}{k - \alpha [M_{\text{an}}(H_\alpha) - M_{\text{irr}}(H_\alpha)]}, \quad (27)$$

which gives the Jiles–Atherton law for irreversible magnetization.

The field-space perspective on hysteresis in uniaxial ferromagnets

A procedure for the analysis of hysteresis in the \mathbf{H} space of a uniaxial ferromagnet with higher-order anisotropy is put forward. The formulation is valid to any order n in the anisotropy expansion. The critical boundaries separating stable from metastable states are cast in a formally decoupled parametric way as $H_x = H_x(M_x)$, $H_z = H_z(M_z)$. The analytic expressions provide the basis for the construction of generalized astroids to any order. For $n > 1$, new features are found and interpreted in their relation to rotational hysteresis and possible spin-reorientation transitions in uniaxial materials. The shape and symmetry of the critical boundaries depend crucially on up to $n-1$ independent ratios of the anisotropy constants against a suitable normalizing quantity; the normalizer can be any from among the set of constants or any linear combination thereof. Self-crossing of an astroid indicates the existence of additional extrema and, hence, of complicated hystereses. © 1998 American Institute of Physics. [S0021-8979(98)23911-9]

I. INTRODUCTION

Hysteresis is a complex nonlinear phenomenon of delicate sensitivity to the past states of the system.¹ In ferromagnets whose anisotropy could be reasonably well characterized by a phenomenologic free energy expansion $F(\theta, \phi)$ in the angular variables of the saturation magnetization \mathbf{M} , hysteresis holds place even if one allows for homogeneous rotation of \mathbf{M} only.² There are certain advantages with the analysis of a uniaxial system in its field space. For instance, one can determine the boundaries of stability of states corresponding to different minima of the anisotropy energy for any field direction and not only for the two principal configurations with field parallel or perpendicular to the axis of symmetry. The case with only the lowest term in the anisotropy expansion has been systematically discussed and implemented.^{1,3} The only exceptions dealing with astroids in higher orders are Refs. 4 and 5 concerning a system with two anisotropy constants. In the following, we demonstrate that this type of analysis is easily extended to any order in the anisotropy expansion due to a special feature of the problem at hand, so that the first two orders are deduced as particular cases. The procedure gives rise to field-space diagrams which will be referred to as generalized astroids. Self-crossing of the boundaries of stability, found already in the second order,^{4,5} arises over large domains of values of the anisotropy constants and is the most pronounced feature of this generalization. It signals the existence of complicated hysteresis behavior due to the emergence of additional competing energy minima.

II. GENERALIZED ASTROIDS: ANALYTICAL AND EXAMPLES

One carries out the field-space analysis with the phenomenological thermodynamic potential of the type $g_A = f_A + \epsilon_Z$, where $\epsilon_Z = -\mathbf{M} \cdot \mathbf{H}$ is the Zeeman term, while

$$f_A(\theta; \{a_j\}) = \sum_{k=1}^{\infty} a_k \sin^{2k} \theta \quad (1)$$

is the full expansion for the anisotropy energy density of a uniaxial ferromagnet.³ The $\{a_j\}$'s are the anisotropy constants of order j , while θ is the angle between \mathbf{M} and the crystallographic axis of cylindrical symmetry \mathbf{n} .

In the assumed symmetry, all three relevant vectors \mathbf{n} , \mathbf{H} , and \mathbf{M} lie in the same plane, since there is no torque to drive the magnetization out of the plane (\mathbf{H}, \mathbf{n}). The remagnetization processes are confined to this plane. This makes all results directly applicable to situations, typical of thin ferromagnetic films, where the magnetization vector is confined within the plane of the film because of the strong dipolar contribution.⁶ We choose the z axis along \mathbf{n} with $\mathbf{M} = (M_x, 0, M_z)$ and $\mathbf{H} = (H_x, 0, H_z)$. To find the stable directions of \mathbf{M} under applied field, one has to look for extrema of $g_A(\theta)$ by solving $g'(\theta) = 0$ and requiring that $g''(\theta) \geq 0$ at the eventual solutions of the extremal equation. In zero field, there is always more than one stable solution, while in sufficiently high fields, the Zeeman energy favors conforming alignment of \mathbf{M} and \mathbf{H} . So the boundaries between perfectly aligned and competing equilibrium states are at some finite magnitude of field which may vary with field direction. It is determined by the simultaneous consideration of the conditions $g'(\theta) = g''(\theta) = 0$ by inserting the expansion from Eq. (1). One observes that this system of two equations is linear in the components of the field, so that, solving for H_x and H_z , one obtains

^{a)}On leave from the CPCS Lab, Inst. Solid State Phys., Sofia; electronic mail: millev@mis.mpg.de

$$H_x = \frac{2}{M} \sum_{k=1}^{\infty} k a_k \sin^{2k-1} \theta [2(1-k) + (2k-1) \sin^2 \theta],$$

$$H_z = \frac{2}{M} \sum_{k=1}^{\infty} k a_k (1-2k) \sum_{p=0}^{k-1} \binom{k-1}{p} (-1)^p \cos^{2p+3} \theta. \quad (2)$$

This is obviously a parametric solution of the type $H_x = H_x(\theta)$, $H_z = H_z(\theta)$ which describes the boundaries of stability in the field space of the uniaxial system to arbitrary order. A seemingly redundant complication has arisen in passing from $\sin \theta$ to $\cos \theta$ in Eqs. (2). This was motivated by the desire to cast the parametric solution in a formally decoupled way as $H_x = H_x(M_x)$, $H_z = H_z(M_z)$. The form serves to identify correspondence rules between the particular principal cases of fields applied along \mathbf{n} or perpendicularly to it. The rules come about by comparing identical powers in M_x and M_z in the two equations for the respective field components. They save half of the labor in exploring the phase diagrams in \mathbf{H} space, since features of given symmetry for a given set of anisotropy constants $\{a_k\}$ must be identical, up to permutation of H_x and H_z axes, for the *corresponding set* of constants. This is in fact a symmetry argument which has escaped attention in the earlier field-space (astroid) studies; here, one deduces it from the general solution to arbitrary order.

A further general observation, valid to any order, is borne out by looking in turn at the two principal configurations $\mathbf{H} \parallel \mathbf{n}$ and $\mathbf{H} \perp \mathbf{n}$. In the first case, the conforming solution ($\mathbf{H} \parallel \mathbf{M}$) is $\sin \theta = 0$ and is stable, to any order, for $H \geq H_{A1}$ with the anisotropy field $H_{A1} = 2|a_1|/M$ depending on a_1 alone despite of considering the contributions from all orders. In the second case, the conforming solution is $\cos \theta = 0$ and is stable for $H \geq H_{A2}$ with $H_{A2} = 2|\sum_{k=1}^{\infty} k \cdot a_k|/M$. As a very interesting consequence, in a system with a spin-reorientation transition, which would occur in a given anisotropic ferromagnet if $a_1 \rightarrow 0$ under variation of some parameter like temperature etc., the anisotropy in the direction of the symmetry axis \mathbf{n} becomes soft ($H_{A1} \rightarrow 0$) which gives rise to a number of peculiarities. Either H_{A1} or H_{A2} may serve as natural normalizing quantities for the generalized astroids to arbitrary order, but the choice is not restricted and may be varied, should particular considerations of simplicity hold in a particular system. Generally, the precise shape of the boundaries in \mathbf{H} space depends on up to $n-1$ constitutive ratios to order n . In principle, the part of a normalizing quantity may be played by any linear combination of anisotropy constants.

The predictive power of the \mathbf{H} -space analysis to higher orders depends crucially on the fact that the tangent construction¹ for the determination of the hysteresis along any route in field space remains valid even with anisotropy constants of higher orders. It is indeed a substitute for the numerical solution of a high-degree polynomial equation. The existence of more competing states as one goes to higher orders in the anisotropy energy gives rise to rather complex generalized astroids whose generation by Eqs. (2) can, however, be performed pretty easily.

FIG. 1. (a) The octopole astroid ($a_1 = -a_2$, $a_3 = 0$). The exceptionally high eightfold symmetry derives from the exchange of stability along this special line in the anisotropy space of the system (Ref. 8). (b) Swallow tails due to softening of the anisotropy axis \mathbf{n} for a system with a spontaneous orientational transition. (c) Generalized astroid for a system with both anisotropy fields gone soft ($a_1 \approx 0$, $a_1 + 2a_2 + 3a_3 = 0$). Note the squarelike aspect of the "mainframe." (d) A generalized astroid with all $|a_{1,2,3}|$ equal ($a_{1,3} < 0$, $a_2 > 0$). Self-crossings of this type imply complicated secondary hystereses.

We proceed to illustrate the general method by several examples up to order $n=3$ in the anisotropy expansion. For bulk systems, the necessity of considering three orders in the expansion for a uniaxial system arises in the analysis of the behavior of the rather important group of highly anisotropic rare-earth-transition-metal compounds.⁷ The examples are indicative of the variety of nontrivial cases which are in store when higher-order anisotropies are non-negligible. Consider the case with $a_3 = 0$ first. A symmetric astroid results when $a_1 = -a_2$ [Fig. 1(a)]. This condition corresponds to the line in the anisotropy space along which a stable canted solution exists ($a_1 < 0$) or there is a pair of coexisting minima of equal depth ($a_1 > 0$).³ The symmetry is exceptionally high with the vertices of the octopolelike astroid lying on a circle.⁸ All cases which are of the self-crossing type may be viewed as resulting from continuous deformations of the most symmetric case upon variation of the ratio a_2/a_1 . Generalizing these observations, the most symmetric astroids to any given order of the expansion will be realized on the manifolds where, in zero field, the eventual minima transform into each other continuously or exchange stability, while coexisting. Now consider the case with $a_2 \neq 0$, $a_1 = a_3 = 0$. This is a two-constant approximation where, additionally, the lowest order contribution goes to zero as would be the case in systems exhibiting orientational transitions in zero field. The behavior in the principal field configurations has been elucidated in great detail.⁹ The astroid in Fig. 1(b) sheds light on the behavior of such a system under an applied field of arbitrary direction. One observes the "softening" of the anisotropy field H_{A1} in that the swallow tails adjacent to

the \mathbf{n} axis run smoothly down to the origin. By the same token, the direction perpendicular to \mathbf{n} will become soft whenever the linear combination of constants defining H_{A2} goes to zero. Thus, swallow tails along the H_x axis will run to the origin on the hyperplanes in the anisotropy space defined by $\sum_{k=1}^n k \cdot a_k = 0$ in order n . This is corroborated by Fig. 1(c) where the condition $a_1 + 2a_2 + 3a_3 = 0$ is imposed. Since a_1 is intentionally very small for this plot, the same figure typifies also the situation at an orientational transition [unlike Fig. 1(b), here $a_3 \neq 0$]. Now both H_{A1} and H_{A2} are zero, hence, the symmetric outlook of the cross between the two complete swallow tails. Note that the "mainframe" of the astroid in Fig. 1(c) is very nearly square-shaped. This last feature comes up also with sets of constants which do not lead to self-crossing; we have observed it, e.g., with $a_2/a_1 \approx -1/8$, $a_3/a_1 \approx 1/2$. The outcome of all constants being equal is presented in Fig. 1(d) ($|a_1| = |a_2| = |a_3|$, $a_{1,3} < 0$, $a_2 > 0$). Complicated self-crossings imply nontrivial secondary hystereses as one already knows from the lower-order treatments.^{4,5}

III. DISCUSSION

The method described above can be used to study the possibility of eliminating undesirable hysteresis in uniaxial materials by applying stress in a suitable direction. The idea has been put forward in the context of cubic magnetostrictive materials,¹⁰ but it applies to any symmetry, in principle. The advantage of the uniaxial setting is that there is a single angular degree of freedom, while in cubic symmetry two such degrees are relevant and the analysis relies on an expansion in small deviations from the symmetry axis. The analysis can be performed most easily for stresses along or perpendicular to \mathbf{n} . Since the stress-induced contribution is always of the lowest order, it shifts a_1 by an amount \tilde{a}_1 . For stress σ along \mathbf{n} , the shift is $\tilde{a}_1 = -\sigma\lambda^{\alpha,2}$ for both tetragonal and hexagonal symmetry; here, $\lambda^{\alpha,2}$ is the magnetostrictive coefficient for the mode of change of length along \mathbf{n} .¹¹ Note that the sign of the shift can be controlled, for a given material (i.e., for a given $\lambda^{\alpha,2}$) by applying tensile or compressive stress. The hysteresis for driving fields along one of the two principal directions can be diminished and, eventually, eliminated if the anisotropy field along the other (conjugate) axis is much smaller than along the direction of the driving field. That is, make one of the axes (say, \mathbf{n}) anisotropically soft by applying stress; then the axis perpendicular to \mathbf{n} is automatically the (relatively) harder one; hence, remagnetization along it would be as closely hysteresis-free as the \mathbf{n} -axis is soft. Since there are two options for the quantities to be modified by stress, H_{A1} and H_{A2} , and two further

options for the sign of \tilde{a}_1 , one recognizes four generic possibilities as a framework for selecting suitable material parameters for prospective applications.

The study of hysteresis by the described generalized-astroid construction is readily applicable to ultrathin ferromagnets as well. In these, there is a strong enhancement of the lowest-order anisotropy due to broken crystallographic symmetry at the surface whereby the anisotropy per surface atom is typically about an order of magnitude larger than in the bulk.¹² In both bulk and thin-film uniaxial systems, the consideration of generalized astroids in applied field may offer valuable insights, especially when a spin-reorientation transition is to be analyzed [cf. Figs. 1(b) and 1(c)]. In the vicinity of such transition points, higher-order anisotropies come into play.

Apart from the prospective applications described in the above paragraphs, the general solution to arbitrary order given in Eq. (2) provides for an overview on the whole problem by: (i) reducing the calculation in any particular order to a *deductive* procedure whereas the $n=1$ and $n=2$ solutions appear as special, *ad hoc* constructions independent of each other; (ii) leading straightforwardly to correspondence rules valid to any order by virtue of the formally decoupled solutions $H_x(M_x)$ and $H_z(M_z)$; and (iii) uncovering to any desired order the possibility for, and the mechanism of, making one of the principal axes anisotropically soft and thus allowing the identification of hysteresis-free conditions. Finally, the field-space perspective should be viewed as complementary to stability analyses in the anisotropy space of the system¹³ whereby only the union of both approaches may yield as detailed description as possible and/or required.

Micromagnetic localization

Ralph Skomski^{a)}

Max-Planck-Institut für Mikrostrukturphysik, Weinberg 2, 06120 Halle, Germany

The localization of nucleation modes in inhomogeneous ferromagnets and its influence on the coercivity are investigated. From the formal analogy between quantum mechanics and micromagnetics follows that anisotropy inhomogeneities may cause localization. The nucleation modes of one-dimensional arrays, such as multilayers composed of hard and soft magnetic materials, are localized even if the superlattice exhibits a nearly ideal periodicity. Gaussian distributions of the layer thicknesses lead to Urbach tails and very low coercivities, but a maximum thickness l_m of the soft layers suppresses the Urbach tails. The related problem of magnetic viscosity leads to a supersymmetric Fokker-Planck description where the time dependence of the magnetization is given by the ground-state mode of a fermionic potential. © 1998 American Institute of Physics. [S0021-8979(98)50911-5]

I. INTRODUCTION

Localization means that the eigenfunctions of a partial differential equation are concentrated in a small volume. A well-known problem is electron localization: metallic wave functions, such as free-electron plane waves, are delocalized, whereas electrostatic correlations and disorder may give rise to Mott and Anderson localization, respectively.¹⁻³ Mott localization is a many-body effect and occurs, for example, if the interatomic distance of a metal exceeds a threshold above which metallic conductivity vanishes. Here we are concerned with the Anderson localization in a random potential.

As discussed for example in Ref. 4, there is a formal analogy between micromagnetics and quantum mechanics. Nuclei in homogeneous ellipsoids of revolution are delocalized, but localization may be caused by magnetic inhomogeneities. This micromagnetic localization is of practical importance because it determines the nucleation of reverse domains and therefore affects the coercivity. An example is oriented nanostructured two-phase permanent magnets such as $\text{Nd}_2\text{Fe}_{14}\text{B}/\text{Fe}$, where very high energy products are expected.⁴⁻⁷ In these structures, the rare-earth-containing hard regions act as a skeleton which stabilize the high magnetization of the soft phase, but nucleation modes localized in extended soft regions tend to destroy coercivity.

A related problem is the time dependence of quantities such as the remanent magnetization (magnetic viscosity). On an atomic level, magnetic viscosity arises from the interaction of the magnetic moments with other degrees of freedom such as lattice vibrations. As emphasized in Ref. 8, the heat bath associated with the nonmagnetic degrees of freedom leads to a Fokker-Planck diffusion of the magnetic moments in the zero-temperature potential E_m . However, even for one-dimensional problems such as the motion of a domain wall in a disordered potential there exists no exact solution.

Here we present an interpretation of micromagnetics in terms of the localization problem. Particular emphasis is put on nucleation modes and long-time magnetic relaxations.

II. LOCALIZATION OF NUCLEATION MODES

For simplicity, we will restrict ourselves to the energy functional

$$E_m = \int \left(A \frac{\nabla \mathbf{M}^2}{M_s^2} + K_1(\mathbf{r}) \frac{M_z^2}{M_s^2} - \mu_0 M_z H \right) d\mathbf{r}, \quad (1)$$

where A is the exchange stiffness and $K_1(\mathbf{r})$ denotes the lowest-order uniaxial anisotropy constant. The magnetostatic self-interaction is approximated by a demagnetizing field, because anisotropy fields $2K_1/\mu_0 M_s$ tend to be much larger than stray fields in hard magnets such as ultrathin films and rare-earth permanent magnets.^{4,9,10} Typical microstructures of interest are shown in Fig. 1.

To obtain nucleation modes we rewrite \mathbf{M} as

$$\mathbf{M}(\mathbf{r}) = M_s \sqrt{1 - m(\mathbf{r})^2} \mathbf{e}_z + M_s \mathbf{m}(\mathbf{r}) \quad (2)$$

FIG. 1. Inhomogeneous structures consisting of magnetically hard (dark) and soft (white) regions. The orientation of the common easy axis is irrelevant as long as it is parallel to the applied magnetic field.

^{a)}Present address: Department of Physics and Astronomy, University of Nebraska, Lincoln, Nebraska 68588-0111.

and expand E_m into powers of the small transverse magnetization component $\mathbf{m} = m_x \mathbf{e}_x + m_y \mathbf{e}_y$. Minimizing E_m then yields

$$-A \nabla^2 \mathbf{m} + 2K_1(\mathbf{r}) \mathbf{m} = -\mu_0 M_s H \mathbf{m}. \quad (3)$$

This equation is degenerate with respect to m_x and m_y , so that we restrict ourselves to any direction in the xy plane. In practice, small deviations from the common c -axis anisotropy (grain misalignment) and magnetostatic interactions break the symmetry and fix the direction of \mathbf{m} .

Equation (3) is reminiscent of Schrödinger's equation for an electron in an electrostatic potential V . In this quantum-mechanical analogy, A , K_1 , and $-\mu_0 M_s H/2$ are analogous to \hbar^2/m_e , V , and E , respectively. The ground-state energy E_0 corresponds to the nucleation field $H = -H_N$, which determines the coercivity of nucleation-controlled magnets.⁴ In the ordered limit, Eq. (3) has been solved for a number of cases.^{4,11-13}

Lowest-order perturbation theory yields^{4,5,9}

$$H_N = \frac{2\langle K_1(\mathbf{r}) \rangle_v}{\mu_0 M_s} \quad (4)$$

so that the nucleation field is given by the volume-averaged anisotropy constant $\langle K_1(\mathbf{r}) \rangle_v = K$. In the quantum-mechanical analogy, this approach is known as the *virtual crystal* approximation.¹⁴

There are various methods to solve the random-potential band structure problem.^{3,14} Here we restrict ourselves to *second-order perturbation theory*. Applying the quantum-mechanical expression

$$E = E_0 + \langle \psi_0 | V | \psi_0 \rangle - \sum_k \frac{|\langle \psi_k | V | \psi_0 \rangle|^2}{E_k - E_0} \quad (5)$$

to Eq. (3) yields

$$\mu_0 H_N = \frac{2K}{M_s} - \frac{4}{(2\pi)^d A M_s} \int \frac{1}{k^2} G(\mathbf{k}) d^d \mathbf{k}. \quad (6)$$

Here $G(\mathbf{k}) = \int \exp(i\mathbf{k} \cdot \mathbf{r}) \cdot \langle [K_1(\mathbf{r}) - K][K_1(0) - K] \rangle_v d\mathbf{r}$ is the Fourier-transformed autocorrelation function of the disorder. For example, the isotropic distribution $\langle [K_1(\mathbf{r}) - K][K_1(0) - K] \rangle_v = K_0^2 \exp(-r^2/2R^2)$ yields $G(\mathbf{k}) = (2\pi R^2)^{d/2} K_0^2 \exp(-k^2 R^2/2)$. In these equations, R is the average radius of the hard and soft regions and $K_0 = K_h \sqrt{f_s(1-f_s)}$, where K_h is the anisotropy constant of the hard phase and f_s is the volume fraction of the soft phase.

Localization depends on the *dimensionality* of the problem and is most pronounced in one and two dimensions.^{1,14} Figure 1 shows some one-, two-, and three-dimensional structures of interest. In Eq. (6), the $1/k^2$ term causes the corrections to diverge in less than two dimensions. This result is related to the absence of metallic conduction in less than two dimensions.^{3,14} For $d > 2$, Eq. (6) yields

$$\mu_0 H_N = \frac{2K}{M_s} - \frac{4R^2}{(d-2)AM_s} K_0^2. \quad (7)$$

The $1/(d-2)$ dependence in this equation shows that three-dimensional configurations of soft and hard regions are not very much affected by minor inhomogeneities. As a rule,

FIG. 2. Nucleation modes in (a) ideally periodic and (b) nearly periodic multilayers. The solid lines show the K_1 profiles in the z direction, while the nucleation modes $|\mathbf{m}(z)|$ are given by the dashed lines.

coercivity breaks down if the size of the soft regions is larger than the domain-wall width $\pi\sqrt{A/K_h} \approx 4$ nm of the hard phase (compare also Refs. 4 and 9).

In one dimension, for example in multilayers, arbitrary small disorder leads to localization. Figure 2 compares delocalized and localized nucleation modes $\mathbf{m}(z)$ in (a) periodic and (b) nearly periodic multilayers. In Fig. 2(b), one soft layer is thicker by about 15% than the others, and the nucleation mode is localized. As in quantum mechanics, there is a small resonance interaction (tunneling) between the potential minima,⁴ but in fair approximation this contribution can be neglected here and following Ref. 4 we estimate that the nucleation field of Fig. 2(b) is smaller by about 30% than that of the periodic lattice Fig. 2(a).

In most cases, disorder leads to extended soft regions which destroy coercivity. In the context of electron localization, the low-lying states responsible for this behavior are known as *Urbach tails*, and asymptotically the density of states of the Urbach tail is given by the probability distribution of the structural disorder.³ In multilayers, a Gaussian distribution of thicknesses l_s of the soft layers yields a logarithmic dependence of the nucleation field on the total film thickness t and yields $H_N = 0$ for $t \rightarrow \infty$.¹⁸ However, if the thicknesses obey $l_s \leq l_m$ then the Urbach tails are cut off and the nucleation field scales as $1/l_m^2$, as sketched for example in Refs. 4 and 13.

III. SUPERSYMMETRY

An atomic approach towards magnetic viscosity is to consider random thermal forces $\xi(t)$ acting on the magnetization vector. For simplicity, we will restrict ourselves to a single magnetization degree of freedom s . Examples are $s = \sin \theta$ and $s = x$ in fine-particle and pinning-type magnets, respectively. This leads to the *magnetic Langevin equation*

$$\frac{\partial s}{\partial t} = -\frac{\Gamma_0}{k_B T} \frac{\partial E_m}{\partial s} + \sqrt{2\Gamma_0} \xi(t), \quad (8)$$

where $\Gamma_0 = 1/\tau_0$ is an atomic attempt frequency.^{8,15,16} The random forces obey $\langle \xi(t) \rangle = 0$ and $\langle \xi(t)\xi(t') \rangle = \delta(t-t')$, where $\delta(x)$ is the delta or "needle" function defined by $\delta(x) = 0$ for $x \neq 0$ and $\int \delta(x)dx = 1$. At low temperatures, the $\partial s/\partial t$ and ξ terms are negligible and Eq. (8) reduces to the trivial minimization problem $\partial E_m/\partial s = 0$.

The probability distribution $P(s, t)$ obeys the magnetic Fokker-Planck equation^{8,15}

$$\Gamma_0^{-1} \partial P/\partial t = (k_B T)^{-1} \partial (P \partial E_m/\partial s)/\partial s + \partial P^2/\partial s^2. \quad (9)$$

As Eq. (1), the Fokker-Planck equation implies that macroscopic magnetization jumps consist of a chain of microscopic events. A simple one-dimensional example are small patches of (111) transition-metal films with easy-plane anisotropy but without in-plane anisotropy, that is $E_m(\phi) = \text{const}$. For the initial condition $\mathbf{M} = \mathbf{M}_s \mathbf{e}_x$ we obtain $P(\phi, t) = (4\pi\Gamma_0 t)^{-1/2} \exp(-\phi^2/4\Gamma_0 t)$ and $\langle \cos \phi \rangle = \exp(-\Gamma_0 t)$. There is, however, no general solution of the one-dimensional Fokker-Planck equation.^{8,15}

In equilibrium, where $\partial P/\partial t = 0$, Eq. (9) yields the relaxation rate $\Gamma = 0$ and $P(s) = Z^{-1} \exp(-E_m/k_B T)$. However, to understand the long-time magnetic-viscosity limit we have to consider the smallest nonzero relaxation rate $\Gamma_1 = 1/\tau_1$. A conceptionally very simple solution of this problem is provided in terms of supersymmetric quantum mechanics, which unifies bosonic and fermionic properties of matter. The observed particle masses indicate a strong breaking of the supersymmetry in elementary particle physics, but the concept is a useful idea not only in elementary particle physics but also in solid-state physics.^{15,17} The formal ansatz $P(s, t) = \exp(-\Gamma t) \exp(-E_m/2k_B T) \Psi(s)$ transforms Eq. (9) into

$$\frac{\Gamma}{\Gamma_0} \Psi = -\frac{\partial^2 \Psi}{\partial s^2} + V_+ \Psi, \quad (10)$$

where the so-called bosonic potential V_+ and its fermionic counterpart V_- are given by

$$V_{\pm} = (\partial E_m/\partial s)^2/4k_B^2 T^2 \mp (\partial E_m/\partial s^2)/2k_B T. \quad (11)$$

In supersymmetric quantum mechanics, replacing V_+ by V_- transforms the "bosonic" differential Eq. (10) into a fermionic equation. Since the first excited eigenvalue of the bosonic problem is equal to the lowest eigenvalue for the fermionic potential,¹⁷ the long-time limit of magnetic viscos-

ity is a ground-state property of the fermionic problem. However, the localization behavior of the fermionic ground-state mode is more complicated than that shown in Fig. 2 and requires further analysis.

IV. DISCUSSION AND CONCLUSIONS

In conclusion, we have analyzed the localization behavior of nucleation and magnetic-viscosity modes in terms of the new concepts of micromagnetic Urbach tails and supersymmetric magnetic viscosity. Nucleation modes in one-dimensional structures, such as multilayers, are localized, even if the structure is nearly periodic. Gaussian disorder destroys coercivity, but a maximum thickness l_{max} of the soft-magnetic layers achieved by careful processing assures a finite nucleation field. On the other hand, we have shown that the long-time limit of magnetic viscosity is equivalent to the ground-state localization in a fermionic supersymmetric potential.

Computational micromagnetic investigation of magnetization reversal in Nd-Fe-B nanocomposite magnets

S. David,^{a)} B. Kevorkian, J. C. Toussaint, and D. Givord

Laboratoire de Magnétisme Louis Néel-CNRS, BP 166, 38042 Grenoble Cedex 9, France

As a complement to the experimental analysis of magnetization reversal in a two-phase system, a numerical micromagnetic three-dimensional calculation is developed and tested. It is applied to a set of 64 nanometer-scale hard ($\text{Nd}_2\text{Fe}_{14}\text{B}$) and soft (Fe_3B) cubic grains. Calculations reproduce qualitatively the experimentally observed processes and allow the relation between the structure and the coercivity mechanism in nanocomposite hard magnetic materials to be better understood.

© 1998 American Institute of Physics. [S0021-8979(98)51011-0]

I. INTRODUCTION

In nanocomposite magnets, a hard medium-magnetization phase and a soft high-magnetization phase are closely intermixed. With the constituent crystallites being of nanometer size, exchange coupling between them allows both high remanence and medium coercivity to be obtained.¹ Due to their high potential for applications, recent investigations were aimed at improving coercivity in these compounds by optimization of the preparation procedures and the compositions.² Moreover, numerical micromagnetic approaches were developed³ to appraise and predict the influence of microstructural features such as grain size on basic magnetic properties such as remanence, coercivity, and $(\text{BH})_{\text{max}}$. But achievement of both high remanence and sufficient coercivity in nanocomposite hard materials remains unrealized.

Recently methods and models which have been developed to interpret coercivity in other hard magnetic materials were employed to identify the relevant physical parameters and mechanisms involved in magnetization reversal in such materials.^{4,5} To gain deeper understanding and with an eye toward quantitative prediction of magnetic performance, a three-dimensional (3D) computational micromagnetic tool was developed to complement these experimental investigations. In this article it is applied to a simple system which models the structure and interactions within the material. The magnetization reversal process which is deduced from calculation is then qualitatively compared with the experimental results; this is considered a fundamental criterion by which to validate the numerical approach.

II. EXPERIMENTAL BACKGROUND

In a recent study,⁵ the magnetic properties of two-phase nanocrystalline magnets were investigated on several alloys. Reversible and irreversible reversal processes were separated by extracting the corresponding susceptibilities from the magnetic measurements. In contrast with the mechanisms found in single-phase magnets, this study revealed that reversal in these systems can be schematically interpreted as a two-step process: the initial magnetization reversal is dominated by reversible processes while irreversible processes,

which characterize the coercivity mechanism, occur at larger field values. Furthermore, the field at which the maximum of irreversible reversal occurs is the relevant physical parameter to be considered in analyzing coercivity; as shown in Fig. 4(b), it is found to be higher than H_c^M (the field at which the magnetization vanishes).

In the following, we use, as a basis for comparison with calculation, the hysteresis cycle (Fig. 3) and magnetic susceptibilities (Fig. 4) measured at 300 K on a material containing approximately 50% (volume) hard $\text{Nd}_2\text{Fe}_{14}\text{B}$ and 50% soft Fe_3B , with a crystallite size ranging between 10 and 30 nm as characterized by transmission electron microscopy (TEM).⁶ A model structure was defined according to these structural features.

III. MODEL SYSTEM

We consider a 3D chessboard arrangement where 32 hard phase grains and 32 soft phase grains are stacked up alternatively (Fig. 1). The main advantage of such a model system compared with others³ is that it allows better control over the numerical errors that are observed using a finite difference approach. A 15 nm grain size was chosen for the both hard and soft phases. The intrinsic parameters common to the two magnetic phases (at 300 K) are the spontaneous magnetization $\mu_0 M_s = 1.61$ T and the exchange constant $A = 12.5 \times 10^{-12}$ J/m. In each grain, the magnetocrystalline anisotropy is assumed to be uniaxial; the anisotropy constants are $K_1 = 4.5 \times 10^6$ J/m³ and $K_2 = 0.66 \times 10^6$ J/m³ for the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase and $K_1 = -0.322 \times 10^6$ J/m³ for the Fe_3B phase. The distribution of the easy axis for the hard grains is chosen randomly and is constrained to be isotropic ($\langle \cos \theta \rangle = 1/2$).

FIG. 2. Scaling transformation of a 2D mesh with a factor $b=2$; the dashed squares correspond to the physical system. (a), (b), and (c) illustrate the different steps involved in the transformation.

IV. NUMERICAL BACKGROUND

In the continuous medium approximation, the Gibbs free energy density $F\{\mathbf{m}(\mathbf{r})\}$ of a ferromagnetic system of magnetization vector $\mathbf{M}(\mathbf{r}) = M_s \cdot \mathbf{m}(\mathbf{r})$ can be written as

$$F\{\mathbf{m}(\mathbf{r})\} = \int_V d^3r \{ A[\nabla \mathbf{m}(\mathbf{r})]^2 - P_k[\mathbf{u}_k \cdot \mathbf{m}(\mathbf{r})] - \mu_0 \times M_s \mathbf{H}_{\text{ext}} \cdot \mathbf{m}(\mathbf{r}) - \frac{1}{2} \mu_0 \cdot M_s \mathbf{m}(\mathbf{r}) \cdot \mathbf{H}_S\{\mathbf{m}(\mathbf{r})\} \}, \quad (1)$$

where P_k is a polynomial which expresses the magnetocrystalline anisotropy energy; $\mathbf{H}_S\{\mathbf{m}(\mathbf{r})\}$ is the stray field due to the magnetostatic volume charges $\rho_m = -M_s \nabla \cdot \mathbf{m}(\mathbf{r})$ and to the surface charges $\sigma_m = M_s \mathbf{m}(\mathbf{r}) \cdot \mathbf{n}$ (\mathbf{n} is the surface normal, pointing outwards). \mathbf{H}_S is derived from a scalar potential ϕ which satisfies the Poisson equation inside the material and the Laplace equation outside it. We used the finite difference method to calculate the potential ϕ associated with a given magnetization distribution $\{\mathbf{m}(\mathbf{r})\}$. The values of $\phi(\mathbf{r})$ and $\{\mathbf{m}(\mathbf{r})\}$ were sampled at the cell centers of a regular cubic mesh with grid spacing h .

Accurate estimates of the potential ϕ normally require the grid to be extended over a large region outside the physical system. A multigrid method has therefore been developed to reduce the size of the external mesh and save calculation time. Let us consider a two-dimensional (2D) bounded square domain D , in which the physical system is enclosed, that is placed on a square mesh of parameter h . We note Γ_h the contour joining the set of outer nodes where ϕ is calculated [Fig. 2(a)]. Let us apply a scaling transformation defined by a factor b (in this case $b=2$). The dilatation of the grid gives a coarse mesh of parameter $2h$ [Fig. 2(b)]. In each of the new cells the magnetization vector is determined as a vectorial average of the magnetization vectors. A contraction of this grid is then performed by the same factor [Fig. 2(c)]. The superposition of the two views of domain D before [Fig. 2(a)] and after transformation [Fig. 2(c)] shows that the boundary Γ_h is now located inside the mesh limited by the contour Γ_{2h} .

By imposing $\phi_{2h}=0$ on Γ_{2h} in the fine mesh of Fig. 2(c), the Poisson equation is solved and a coarse estimation of the solution $\{\phi_{2h}\}$ in each cell is obtained. $\{\phi_h\}$ on Γ_h is then calculated by a linear interpolation of $\{\phi_{2h}\}$. The system is then re-expanded to its initial size keeping constant the estimate values of $\{\phi_h\}$ on Γ_h . By again solving the Poisson equation, a better estimate of $\{\phi_h\}$ than that for the

case $\phi_h=0$ on Γ_h is obtained. The method illustrated here for 2D systems have been applied to 3D systems. Our simulations use a grid spacing $h=12.5 \text{ \AA}$ such that $h < \delta_w$ and $h < \delta_{\text{ex}}$ are verified. The nanocomposite structure, made of 64 grains, is discretized by $32 \times 32 \times 32$ elements centered within a box of width $48h$ that surrounds it.

In static field calculations, magnetization configurations in the equilibrium state are determined by integrating the dynamic Landau-Lifshitz-Gilbert (LLG) equation:

$$\frac{d\mathbf{m}}{dt} = -\mathbf{m} \times \mathbf{H}_{\text{eff}}(t), \quad (2)$$

with

$$\mathbf{H}_{\text{eff}}(t) = \mathbf{H}(t) + \alpha \cdot \mathbf{m}(t) \times \mathbf{H}(t), \quad (3)$$

where α is the Gilbert damping constant and $\mathbf{H}(t)$ denotes the functional derivatives of the magnetic energy $F\{\mathbf{m}(\mathbf{r})\}$ with respect to \mathbf{m} . At equilibrium, the torque created by the effective field on the magnetization vector must vanish at each point in the physical system. The evolution of \mathbf{m} turning around the vector field $\mathbf{H}_{\text{eff}}(t)$, governed by Eq. (2), may be described by

$$\begin{aligned} \mathbf{m}(t + \delta t) = & \mathbf{m}(t) \cos(H_{\text{eff}}(t) \delta t) \\ & + \frac{\sin[H_{\text{eff}}(t) \delta t]}{H_{\text{eff}}(t)} [\mathbf{H}_{\text{eff}}(t) \times \mathbf{m}(t)] + [1 \\ & - \cos(H_{\text{eff}}(t) \delta t)] \frac{\mathbf{H}_{\text{eff}}(t) \cdot \mathbf{m}(t)}{H_{\text{eff}}^2(t)} \mathbf{H}_{\text{eff}}(t). \end{aligned} \quad (4)$$

This relation tends towards an exact integration of the LLG equation in the limit of a weakly time-dependent effective field \mathbf{H}_{eff} . This scheme of integration is at least as accurate as the modified Euler method, in which the Taylor expansion must be truncated at second order. It is also more efficient, since it requires only that the first order time derivative be evaluated and, moreover, it allows the magnetization modulus to be maintained constant. As with any explicit method,⁷ numerical instabilities may be encountered and may lead to mistaken solutions to the LLG equations. A stability criterion may be determined for ferromagnetic systems which are mainly governed by exchange interactions. Let us consider a chain of spins located on a Ox axis and directed along Oz . When the system is weakly perturbed, the LLG equations may be linearized. The Von Neumann analysis of the stability consists in developing any numerical fluctuation into a Fourier series and to examine the time evolution of the amplitude $\epsilon_k(t)$ of each mode k . The integrating scheme for a given time step δt is considered to be stable as the gain $G = |\epsilon_k(t + \delta t)/\epsilon_k(t)|$ remains lower than 1. The analysis shows that a time step limit exists and is defined by

$$\delta t_{\text{lim}}^{\text{1D}} = \frac{h^2}{8A} \mu_0 M_s \frac{2\alpha}{1 + \alpha^2}. \quad (5)$$

For 3D systems, a similar analysis leads to $\delta t_{\text{lim}}^{\text{3D}} = \frac{1}{3} \delta t_{\text{lim}}^{\text{1D}}$. An upper limit of $\delta t_{\text{lim}}^{\text{3D}}$ is obtained by choosing $\alpha=1$. This value was chosen in our calculations in order to save computational time.

FIG. 3. Calculated (bold lines) and experimental (dotted line) hysteresis curves in the range $[-2, +2]$ T. The black dots correspond to the calculated equilibrium states of magnetization.

V. RESULTS

The hysteresis curve (Fig. 3) was obtained after calculating the initial polarization of the system in a 4 T external field applied along the Oz axis. The black dots represent the equilibrium magnetization states within the field range $[-2, +2]$ T. A continuous curve was then defined by interpolating it from calculated points; it was used to evaluate the total magnetic susceptibility χ_{tot} as the derivative of magnetization with respect to the applied field [Fig. 4(a)]. Since the simulation enables the contributions to the total magnetization by the two magnetic phases to be distinguished, the hysteresis curve and the susceptibility were also obtained for both hard (χ_{hard}) and soft (χ_{soft}) phases. Moreover, the reversible contribution to the total susceptibility, χ_{rev} , was determined using a procedure which mimicks the experimental method, i.e., by evaluating the slope of the magnetization on successive recoil loops (10 mT) along the major cycle. The quantity $\chi_{\text{tot}} - \chi_{\text{rev}}$,⁴ which is predominantly associated with irreversible reversal phenomena, can thus be deduced.

The calculated ratio M_r/M_s (0.68) is found to be close to the experimental value (0.73). In addition, the calculated hysteresis curves of the hard and soft phases (Fig. 3) clearly show that the reversal process in the second and third quadrants is not homogeneous: the reversal of the soft phase dominates at low field ($H \leq H_c^M$) and that of the hard phase at higher fields ($H > H_c^M$).

The susceptibilities that were derived from simulation [Fig. 4(a)] reveal that (i) the maxima of the reversible and irreversible reversals occur at distinct field values, leading to the fact that (ii) H_c^M is lower than the field value corresponding to the maximum of irreversible reversals. These features are in agreement with the experimental results [Fig. 4(b)] and Sec. II. However, the calculated ratio $\chi_{\text{rev}}/(\chi_{\text{tot}} - \chi_{\text{rev}})$ is much smaller than the experimental values. This result means that a lower proportion of magnetic moments reverse reversibly within the model system than in the real one. From the field dependence of χ_{soft} and χ_{hard} , it appears that about half of the soft moments and the majority of the hard

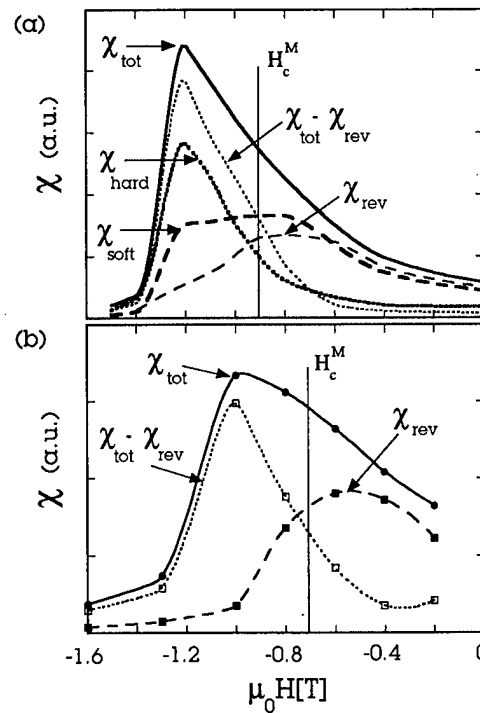

FIG. 4. Calculated (a) and measured (b) magnetic susceptibilities.

moments reverse around the same field value of 1.2 T. This shows that the majority of the soft moments is strongly exchange coupled to the hard moments and is forced to follow their rotation. This phenomenon can be ascribed to the fact that the grain size taken in the present calculation ($D = 15$ nm) tends to be smaller than experimental values (D ranging between 10 and 30 nm, from TEM). Thus, the coupling between the hard and soft phases is stronger than it is in the real system. In turn, the calculated coercivity is larger than it is in the real system and this result suggests that the coercivity of nanocomposite materials can be improved by favoring a small and homogeneous size of the constituent crystallites. This observation is in agreement with the optimal grain size for both coercivity and remanence enhancement that was determined numerically by different authors,⁸ and which is close to 10 nm.

Influence of the system parameters on the non-Arrhenius magnetic relaxation of systems having distributed properties

We have investigated, in the framework of the micromagnetic approximation, the relaxation behavior of both simple systems and systems having distributed properties. In the case of single-particle-type systems, our study focused on the exchange constant dependence of the so-called "waiting time" for the onset of the relaxation to conclude that this parameter linearly increased with the increase of the exchange constant. Our results for the relaxation of polycrystalline-type systems having distributed anisotropy easy axes showed the occurrence in limited time ranges of a magnetization decrease which was adequately fitted by the $M(t) - M(0) \propto \ln(t+t_0)$ law. The exchange constant dependence of the additive fitting parameter in the logarithmic law qualitatively reproduced that of the waiting time indicating that both parameters were linked to the same underlying characteristic of the demagnetization process: the coupling of the magnetic moments forming the domain-wall-like structures through which the system reversed its magnetization. © 1998 American Institute of Physics. [S0021-8979(98)33411-8]

The occurrence of magnetic relaxation¹ is typically identified with the observation of a time variation of the magnetization of a sample which is kept under constant applied demagnetizing field and temperature. The interest on magnetic relaxation is related to two main problems: the experimental study of the behavior of systems having high structural homogeneity and reduced dimensionality (as thin films, multilayers, and sets of nanoparticles^{2,3}); and the analysis of the behavior of very simple systems as isolated particles.⁴ Whereas the first point is of major relevance for the magnetic recording technology, the second one could allow the understanding of the basic relaxation mechanisms of systems having many degrees of freedom.⁵ The conventional analysis of the magnetic relaxation processes⁶ assumes that (i) the system can be replaced by a set of noninteracting subsystems with two-level-type behavior, and (ii) each subsystem relaxes according to the Arrhenius kinetics. This treatment has some relevant limitations: (i) it ignores the fact that the field induced magnetization reversal involves several stages in the nucleation-expansion-propagation-pinning sequence,⁷ (ii) it does not provide any explicit relationship between the relaxation behavior and the defect distribution of the sample, (iii) it ignores any exchange and dipolar interactions, and (iv) arbitrarily assumes a particular relaxation kinetics mainly invoked to account for the quasilogarithmic relaxations ubiquitously observed in hard magnetic materials.⁸ Regarding these limitations the authors have recently discussed in several works⁹ the behavior of simple systems in terms of free energy micromagnetic models. In these works it is shown that the thermally activated magnetization reversal cannot be described in terms of the Arrhenius predictions since, similarly to hysteresis, it takes place through a nucleation-propagation process and involves a "waiting time" during which the macroscopic state of the system varies slowly.

Recent experimental results,¹⁰ obtained in highly homogeneous thin films, evidence the actual occurrence of the basic relaxation features predicted in Ref. 9. Our purpose in the present work was to investigate the system parameter dependence of the relaxation behavior of model polycrystalline systems and to compare the obtained results with those corresponding to simple systems. The considered models⁹ consist of a long chain of infinite parallel planes. The internal energy of the systems includes anisotropy, Zeeman, exchange, and magnetostatic interactions.⁹ The intrinsic properties of our system are described by the following parameters: (i) the exchange energy-to-anisotropy energy ratio, $a = Ad^{-2}/2K$ (where A is the exchange constant, d is the interplanar distance, and K the uniaxial anisotropy constant); (ii) the square of the magnetization-to-anisotropy energy ratio, $m = \mu_0 M_s^2/2K$ (where M_s is the saturation magnetization), and (iii) the reduced applied field, $h = \mu_0 M_s H/2K$ (where H is the applied field directed along the z direction of our reference system). We have considered two different types of systems: (a) single-grain-like systems having homogeneous easy anisotropy axis and (b) polycrystalline-like systems which are divided in 100 "grains" (each one having 50 planes). In the case of the polycrystalline-like systems the easy directions corresponding to the different grains are uniformly distributed in a cone having an apex angle of α degrees and a symmetry axis parallel to the Z . In the single-grain systems the easy axis is contained in the YZ plane and forms a 10° angle with the Z direction. Our simulations were carried out at a temperature corresponding to 10^{-4} of the maximum anisotropy energy per unit surface attainable by the system. The field and time evolution of the system configurations was followed by minimizing their energy by means of a Monte Carlo algorithm implemented with Metropolis dynamics. In this context, we define a Monte Carlo

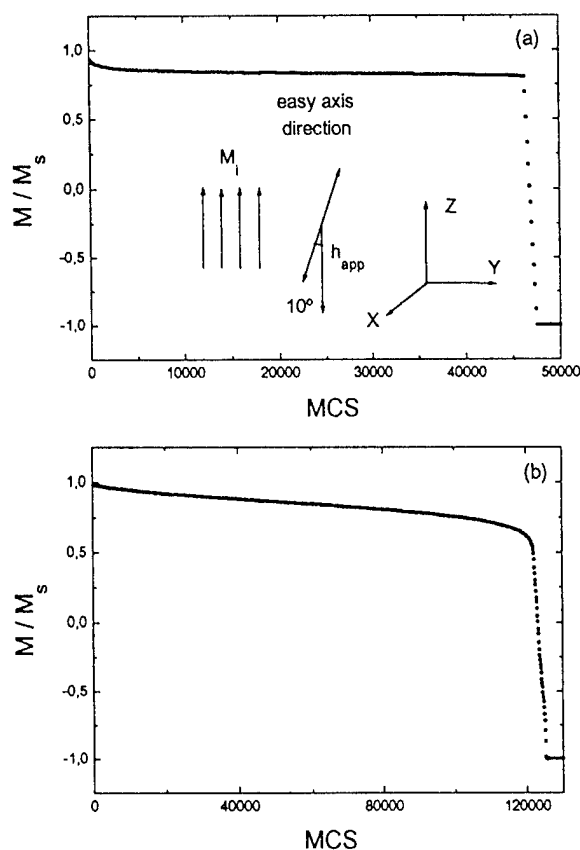

FIG. 1. Typical evolution, at constant applied field, of the reduced magnetization with the number of MCS. Single-grain systems: (a) $a=2$, (b) $a=20$ ($m=0.15$).

step (MCS) as the process corresponding to the introduction of a random modification in all degrees of freedom of the system. If the attempt frequency for those modifications is known (through an independent argument), the number of MCS can be converted in real-time units. In Figs. 1(a) and 1(b) we present results corresponding to the (time) MCS evolution of the magnetization of two single-grain-like systems having exchange-to-anisotropy ratios of 2 and 20, respectively (see the other system parameters in the caption). The relaxation curves were obtained under a constant reduced field $h=0.99h_c$ (h_c being the coercive force of the system, evaluated from the $+Z$ saturated state, by considering a field decrement of $\Delta h=10^{-3}$ and a relaxation stage of 1500 MCS). In both systems, the occurrence of a waiting time and that of a complete magnetization reversal in a finite number of MCS are apparent. As previously discussed⁹ both facts are related to the accomplishment of magnetic relaxation through a process involving the nucleation and propagation of domain-wall-like structures. Figure 2 presents our results for the dependence on the exchange-to-anisotropy ratio of the waiting time observed in single-grain-like systems. The observed linear increase of the waiting time is related to the increase, with the parameter, of the number of moments involved in the wall structures responsible for the magnetization reversal (the typical number of moments forming these structures varies with a as $a^{1/2}$). Figures 3(a) and 3(b) present relaxation results corresponding to polycrystalline-like systems having different exchange-to-anisotropy ratios.

FIG. 2. Single-grain system. Variation of the waiting time with the exchange-to-anisotropy ratio.

These results were obtained under a reduced applied field $h=0.97h_c$ (h_c was evaluated as detailed above). Similarly to the case of the single-grain-like systems, it is possible to observe in these figures a time interval of slow demagnetization rate and the accomplishment of complete relaxation in a finite time. In Figs. 4(a) and 4(b) we have plotted in a logarithmic scale the relaxation data presented in Figs. 3(a) and 3(b). As it is possible to observe in these figures a logarithmic law is not adequate to describe the whole relaxation process (as, for instance, a stretched exponential would be) but it describes reasonably well the (time) MCS region cor-

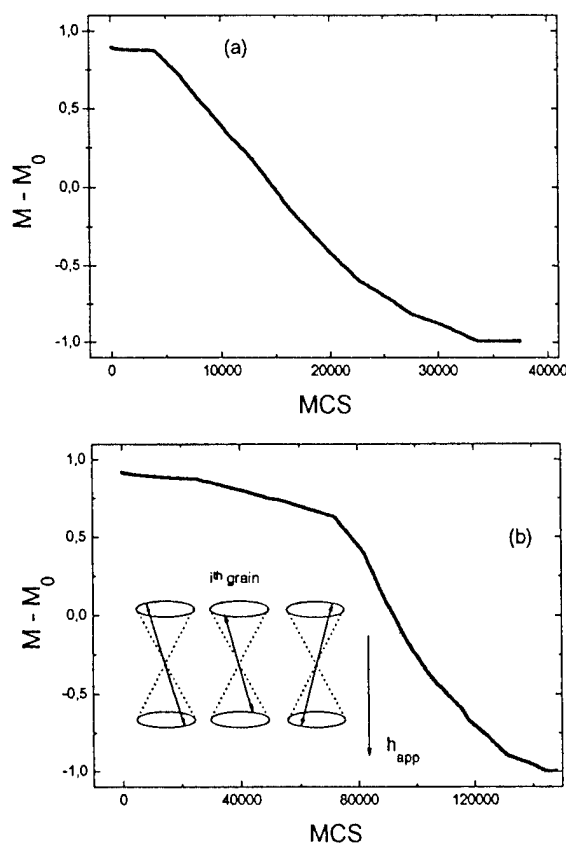

FIG. 3. Typical evolution, at constant applied field, of the reduced magnetization with the number of MCS. Polycrystalline system: (a) $a=2$, (b) $a=20$ ($m=0.15$).

responding to the highest demagnetization rates (indicated in the figures by large symbols). In fact, the law giving the best fit to our data in these regions is given by $M(\text{MCS}) - M(0) = -S \ln(\text{MCS} + \text{MCS}_0)$, where the MCS_0 fitting parameter translates the occurrence of a slow demagnetization regime. This point has been evidenced through to different simulations. In Fig. 5 we present the MCS_0 dependence on the exchange-to-anisotropy ratio which qualitatively repro-

FIG. 5. Polycrystalline system. Variation of the MCS_0 parameter with the exchange-to-anisotropy ratio.

FIG. 6. Variation of MCS_0 with the degree of texture (MCS_0 is normalized to MCS^*), the waiting time value corresponding to a single-grain system having the same model parameters.

duces that observed in the case of the single-grain-like systems. The magnitude of MCS_0 is about five times smaller than that obtained for the waiting time (considering the same system parameters) in the case of the single-grain-like systems. Nevertheless, direct comparison of both sets of results is not possible due to the fact that in the polycrystalline-like systems significant inhomogeneities are present, due to the easy axes distribution, in the magnetic moment configurations corresponding to the remanent states and these inhomogeneities are effective as wall nucleation centres.⁹ Figure 6 shows our results for the MCS_0 dependence on α (the parameter measuring the degree of texture of the polycrystalline-like systems). The data in the figure (obtained for $h = 0.95h_c$, $a=2$, $m=0.15$) were normalized to MCS^* , the waiting time corresponding to a single-grain system having the same model parameters. MCS_0 increases with the decrease of α (that is with the increase of the degree of texture) evidencing its relationship to the degree of order of the remanence moment configuration from which the thermally activated reversal proceeds.

Voltage dependence of magnetoresistance in spin dependent tunneling junctions

J. Zhang and R. M. White^{a)}

*Data Storage Systems Center, Department of Electrical and Computer Engineering,
Carnegie Mellon University, Pittsburgh, Pennsylvania 15213*

The voltage dependence of magnetoresistance in spin dependent tunneling (SDT) junctions was studied experimentally and theoretically. Different magnetoresistance (MR)- V dependence in various patterned junctions was observed and correlated with other technologically important parameters, including the magnitude of the MR, linearity of the current-voltage characteristic, temperature dependence of the junction resistance, and the MR. A phenomenological model based on a spin-independent two-step tunneling via defect states in the barrier, in addition to the spin-dependent direct tunneling, is proposed to account for the MR- V dependence. The MR ratio is determined by the ratio of the two currents. The MR- V dependence results from a stronger voltage dependence of the two-step tunneling current compared to that of the direct tunneling current. The same model also satisfactorily predicts other properties of SDT junctions. A high quality barrier is required to minimize the MR- V dependence and improve other junction properties. The approach to achieving desirable junction impedance for data storage applications is discussed. © 1998 American Institute of Physics. [S0021-8979(98)28311-3]

I. INTRODUCTION

Tremendous progress has been made recently in achieving high room temperature magneto (MR) ($\sim 20\%$) in microstructure spin dependent tunneling (SDT) junctions at low field.^{1,2} However, there is a lack of understanding for one of the most puzzling features of SDT junctions, i.e., the voltage dependence of the MR. Although the detailed voltage dependence of the MR varies from junction to junction, the MR generally decreases as the voltage increases and falls to half of the low bias MR at a voltage of several hundred millivolts.³ Understanding this effect is not only critical to optimize SDT device performance for potential data storage applications, but also provides critical insights into magnetotransport properties of SDT junctions. This article studies the MR- V dependence experimentally and theoretically. A simple yet effective model based on a second tunneling mechanism, in addition to the ideal direct tunneling, is proposed for the first time to interpret the MR- V dependence and its correlation with other technologically important properties of SDT junctions.

II. EXPERIMENTS AND RESULTS

SDT trilayers with the structure ferromagnetic (FM)/FM were sputter deposited on Si substrates with a thermally oxidized surface in a Perkin-Elmer 2400-8L sputtering system. The insulating barrier AlO_x was formed by oxidizing an ultrathin Al layer in an Ar/O_2 plasma. A magnetic field was applied during deposition to define a uniaxial anisotropy of the FM layers. Sheet films show clear magnetic

loop separation, indicating a weak interlayer coupling. They were subtractively patterned into SDT junctions using a photolithographic process similar to other reported approaches.⁴ Precautions were taken during the processing to avoid shorting of top and bottom electrodes near junction edges, breakdown of oxide barriers, and unreliable contact between leads and electrodes. These actions guarantee that subsequent measurements reveal the intrinsic junction properties.

Two groups (A and B) of SDT junctions were studied for comparison. Both groups have the structure $\text{Si}/\text{SiO}_2/\text{FM1}(125 \text{ \AA})/\text{Al}-\text{AlO}_x/\text{FM2}(150 \text{ \AA})$, where FM1 can be NiFe or NiFeCo, and FM2 can be Co or CoFe. The major difference between the two groups lies in the oxide barrier. The 17 Å barrier in group A was formed by glow discharge⁵ with a high cathode voltage of around -1000 V . The 20 Å barrier in group B was formed by oxygen plasma etching⁶ with a low substrate voltage of -40 V . Sheet films in group A were deposited at Nonvolatile Electronics, Inc. (NVE) and patterned into devices at CMU. The MR was measured using a dc four-probe method. Most junctions show a clean MR- H response. The room temperature MR at low voltage ranges from below 1% to as high as 17%. The current-voltage (I - V) characteristics and the MR- V dependence were obtained by sweeping the voltage from 10 to up to 500 mV. The temperature dependence data were acquired by heating the junction with flexible heaters to up to 100°C .

The junctions in these two groups show very different behavior. Junctions in group A show a high MR of up to 17% at room temperature, while junctions in group B show a much lower MR. On the other hand, the MR of group B junctions show a much stronger voltage dependence than group A junctions. Typical MR- V dependencies are plotted

^{a)}Electronic mail: white@gauss.ece.cmu.edu

FIG. 1. Typical room temperature MR-V dependence of junctions in groups A and B. MR is normalized to low bias MR for comparison. Dashed lines show model predicted MR-V dependence.

in Fig. 1. This is consistent with the correlation of MR-V dependence and MR observed by other groups.¹ Unlike other reported results,³ however, no large asymmetry with regard to the bias polarity was observed. The I - V characteristics of group B junctions are more nonlinear than group A junctions, as shown in Fig. 2. A decrease of the MR at increased bias is accompanied by the onset of pronounced nonlinearity. In addition, the resistance and the MR of group B junctions show a much stronger temperature dependence compared to group A junctions, as shown in Figs. 3 and 4. This experimental data indicates a correlation between the MR, the I - V characteristic, and the MR-V, MR-T, and R-T dependencies. We shall propose a simple yet effective theory to explain these correlations.

III. A PHENOMENOLOGICAL MODEL

The spin dependent tunneling theory by Julliere⁷ at low temperature and voltage is widely accepted. The theory assumes direct tunneling with no spin flipping. However, the theory based on this assumption fails to explain the voltage and temperature dependence of junction properties. For example, the predicted temperature coefficient of the junction resistance is on the order of $-0.1\%/^{\circ}\text{C}$, much less than observed for group B junctions. The calculated MR-V and

FIG. 2. Typical I - V characteristics of junctions in two groups. The resistance is normalized to the low bias resistance for nonlinearity comparison.

FIG. 3. Temperature dependence of junction resistance. The resistance is normalized to R_{T1} at room temperature.

MR-T dependence is also much weaker than experimental results. The discrepancy suggests that other factors, such as other tunneling mechanisms or spin flipping processes, must be considered to complete the description.

The strong R-T dependence shown by group B junctions, which is not predicted by the conventional tunneling theory, suggests a thermal activation process. We suggest that there exist localized defect states in the barrier. Excitation of electrons from these states, either thermally or by hot electron impact, create states available for two-step tunneling,⁸ as shown in Fig. 5. Because these thermally generated states are not polarized, the two-step tunneling is spin independent and does not contribute to MR. The MR is reduced by this spin-independent current and can be expressed as

$$MR = \frac{(I_{\text{para}} - I_{\text{anti}})/I_{\text{anti}}}{1 + I_2/I_{\text{anti}}} \sim \frac{MR_{\text{max}}}{1 + I_2/I_{\text{anti}}}, \quad (1)$$

where I_2 is the current carried by the two-step tunneling. I_{para} and I_{anti} are spin dependent currents carried by the direct tunneling when magnetic moments are parallel and antiparallel, respectively. $MR_{\text{max}} \sim (I_{\text{para}} - I_{\text{anti}})/I_{\text{anti}}$ is approximately the MR given by Julliere's model⁷ when there is no

FIG. 4. Temperature dependence of MR normalized to room temperature MR.

FIG. 5. Schematic view of the two-step tunneling via defect states.

spin mixing. It is clear that the ratio of the spin-dependent and spin-independent currents determines the MR. If the tunneling current is mainly carried by the two-step tunneling, a low MR is expected. It should be pointed out that other factors, such as a thick layer of unoxidized Al layer, also lead to a low MR. However, this possibility has been ruled out in our case by the process control.

The voltage and temperature dependence of the two-step tunneling current is the key to understanding the voltage and temperature dependence of junction properties. For simplicity, it is assumed that the defect states in the barrier are uniformly distributed, both spatially and energetically. The energetic distribution of the available defect states is governed by a Fermi-Dirac function

$$f(E) = \frac{1}{1 + \exp[(E_c - E)/kT_{\text{eff}}]}, \quad (2)$$

where E is the energy level of the defect state, E_c is the energy level of the barrier conduction band edge, k is the Boltzmann constant, and T_{eff} is the effective barrier temperature. As suggested by Eq. (2), the density of available states increases exponentially as the energy level increases. Therefore, the two-step tunneling current, which is proportional to the vacant defect state density, increases quickly at an increased bias voltage. The two-step tunneling current calculated by this model quickly exceeds the direct tunneling current at increased voltage. This leads to a decrease in the MR, according to Eq. (1). This model also indicates that the two-step tunneling is mainly responsible for the nonlinearity of the I - V characteristic. Therefore, the observed correlation of MR, MR- V dependence, and I - V characteristic can be explained.

T_{eff} is a parameter in this model. It determines the nonlinearity of the I - V characteristic of the two-step tunneling, and therefore, the MR- V dependence. Our fit to the MR- V dependence data at room temperature in Fig. 1 gives a value of kT_{eff} of the order of 0.2 eV. This T_{eff} is higher than the ambient temperature, and is possibly due to the presence of hot electrons in the barrier. In metal-oxide-semiconductor (MOS) devices, trap state generation in the gate oxide is enhanced by high electric fields and temperature.⁹ Similarly, T_{eff} for SDT barriers is expected to increase with the voltage

bias and the temperature. Based on the results from hot electron studies, we have assumed a form for $T_{\text{eff}}(V, T)$ given by

$$kT_{\text{eff}} = \sqrt{(CkT)^2 + [eV_1 \exp(V/V_2)]^2}, \quad (3)$$

where V_1 , V_2 , and C are free parameters which depend on the material properties of the barrier. The first and the second term in the square root represent the effect of temperature and voltage, respectively. C represents the indirect effect of temperature on the excitation process¹⁰ and can be determined from the temperature dependence data, while V_1 and V_2 can be determined from the voltage dependence data. This expression was found to fit the experimental data reasonably well for voltages between 10 and 500 mV. The predicted MR- V dependence based on this model is plotted in Fig. 1. The parameters used are $C=3.0$, $V_1=0.2$ V, and $V_2=10.0$ V. Different ratios of the spin-dependent and the spin-independent currents are required for junctions in group A and B.

It can be shown that the two-step tunneling has a stronger temperature dependence than the direct tunneling. Therefore, the temperature dependence of the junction properties can also be explained by this model. These details are covered elsewhere.¹⁰

IV. DISCUSSIONS AND CONCLUSIONS

Based on the model discussed in Sec. III, the current in group A (B) junctions with a high (low) MR is mainly carried by the spin-dependent direct tunneling (spin-independent two-step tunneling). Though other factors might lead to the observed voltage and temperature dependence of junction properties,¹ it is believed that this dependence is mainly attributed to the nonperfect nature of the barrier and the strong voltage and temperature dependence of the two-step tunneling. Therefore, the key to improving the MR and minimizing the voltage and temperature dependence is high quality barriers with low defect state density. In particular, a thin barrier is preferred to a low barrier as this will also reduce the resistance of the junction.

We have studied systematically the magnetotunneling properties of several metallic magnetic-tunnel-junction systems ($\text{Ni}_{80}\text{Fe}_{20}$ -insulator- $\text{Ni}_{80}\text{Fe}_{20}$, $\text{Ni}_{80}\text{Fe}_{20}$ -I-Co, Co-I-Co, $\text{Ni}_{40}\text{Fe}_{60}$ -I-Co). The room-temperature magnetoresistance MR value at zero-bias ranges between 16% and 27%, depending on the spin polarization of the electrodes. There seems to be a general bias dependence of MR in all of these systems. In particular, it requires a bias in the range of 0.22–0.23 V to suppress the maximum MR value by half. We have also measured the bias dependence of MR as a function of barrier parameters (thickness and oxidation time). At low temperature, a sharp cusplike feature appears near zero bias. In some cases, low-temperature MR values substantially exceed expectations from established spin-polarization. © 1998 American Institute of Physics.

Magnetic-tunnel junctions (MTJs) are emerging as a new class of magnetoresistive (MR) devices.^{1–7} MTJs have demonstrated a number of technical advantages over the existing giant magnetoresistance (GMR) devices. Metallic GMR structures are inherently highly conductive, so a large current density is required to generate enough voltage signal. For a tunnel junction, however, device resistance can in principle be controlled by barrier parameters.

Magnetic-tunnel junctions have been studied since the 1970s.¹ One of the perplexing properties observed since then is a strong suppression of magnetoresistance with bias voltage on a junction.^{5,8–10} This bias voltage dependence could convey information about the detailed process of spin-polarized tunneling. In this paper, we present an on-going study of the bias voltage and temperature dependence of MTJs particularly with transition metals and alloys as both electrodes.

The magnetic-tunnel junctions employed in this study are made by magnetron sputtering. The base pressure of the deposition system is lower than 1×10^{-8} Torr. A typical layer sequence is represented in Fig. 1(a). A thin layer of Al was deposited and subsequently plasma oxidized in the chamber to form the tunnel barrier. The nominal thickness of this Al layer is in the range of 5–15 Å. The oxygen pressure during oxidation is 100 mTorr, and oxidation times range from 30 s to 7 mins. A ferromagnet–antiferromagnet–ferromagnet (FM–AFM–FM) sandwich structure is deposited to provide exchange biasing for the bottom electrode. This technique separates the magnetic response of the top electrode from that of the bottom, and enables us to attain saturated antiparallel configurations of the junction. After the deposition, a lithographical patterning procedure was used to fabricate the MTJ devices as small as $1 \times 1 \mu\text{m}^2$. The details of this process have been described elsewhere.^{5–7}

The blanket multilayer films are examined by a

vibrating-sample magnetometer at room temperature after the deposition. Figure 1(b) shows a typical result. Three distinct hysteresis loops of varying sizes can be clearly seen, corresponding to the three ferromagnetic layers in the FM–AFM–FM sandwich structure of the bottom electrode, and have been shifted due to the exchange biasing effect. The centered hysteresis loop is generated by the top electrode. For more details about the magnetic properties of MTJs, refer to Refs. 5 and 6.

The hysteresis loops of the two electrodes are well reproduced by the tunneling resistance of the junction, as shown in Fig. 2(a). Between the hysteresis loops, the magnetization of the electrodes are antiparallel to each other, and junction resistance is maximized due to the mismatch of spin-polarized bands across the tunnel barrier. At higher field in either direction, the electrodes are aligned to be parallel and junction resistance reduces to a minimum value. This magnetoresistance effect can be understood qualitatively in the framework of the two-current model, first proposed by

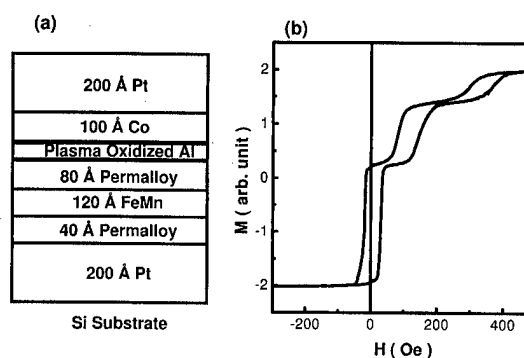

FIG. 1. (a) Layer sequence of a typical MTJ junction with exchange biased bottom electrode, and (b) the magnetization curves of one blanket multilayer film consisting of the MTJ structure. Three distinctive hysteresis loops can be seen corresponding to the three ferromagnetic layers in the film.

(c) Magnetoresistance, calculated using the differential resistance data, as a function of dc bias.

Julliere.¹ Assuming the two spin species of electrons tunnel through the barrier independently, the two-current model predicts the magnetoresistance, defined as the difference in resistance divided by the minimum value, as

$$\frac{\Delta R}{R_P} = \frac{R_{\uparrow\downarrow} - R_{\uparrow\uparrow}}{R_{\uparrow\uparrow}} = \frac{J_P}{J_{AP}} - 1 = \frac{1 + P_1 P_2}{1 - P_1 P_2} - 1 = \frac{2 P_1 P_2}{1 - P_1 P_2}, \quad (1)$$

where P_1 and P_2 are the spin-polarization factor of the two electrodes. The spin polarization of a number of materials has been measured in a series of tunneling experiments between ferromagnets and superconductor (FM-I-S) by Meservey and Tedrow.¹¹ We will later assemble a comparison of our results with these spin-polarization factors.

The simple two-current model does not take into consideration the effects of electron band structure, tunnel barrier transmission, and spin-flipping excitations into consideration, and thus, predicts no bias voltage dependence for the magnetoresistance. Experimenters,¹⁻⁴ however, have always observed a substantial decrease in MR with the application of bias. The differential resistance in parallel (solid) and antiparallel (dashed) states as well as the MR of one of our junctions are plotted versus dc bias in Fig. 2(b). The bias dependence of the differential resistance has the general feature of a metal-insulator-metal tunnel junction in that resistance decreases with bias and has a smooth maxima close to zero bias. The detailed shape of the curve shows deviations from simple calculations such as Simmons's formula.

We have measured the bias dependence of R and MR in MTJs with various electrode material and barrier parameters. The results are summarized in Figs. 3(a) and 3(b). Figure

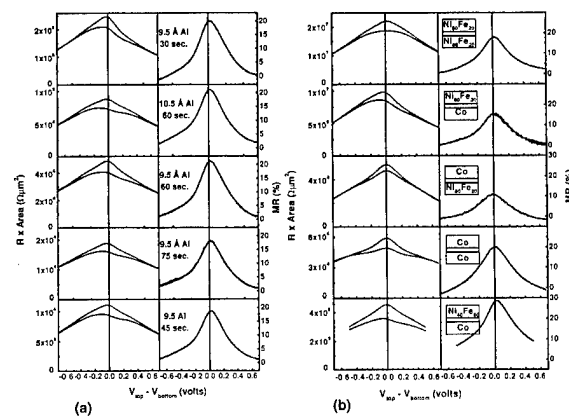

FIG. 3. (a) Bias dependence (room temperature) of junction resistance in both parallel (solid) and antiparallel (dashed) configurations and MR in a series of junctions with a Co base electrode and $\text{Ni}_{80}\text{Fe}_{20}$ counter electrode, but different barrier fabrication conditions (shown in the insets). (b) Same plots as (a) for a series of junctions with various electrode material combinations (shown in the insets).

3(a) plotted the bias dependence of R and MR in a series of junctions all with a Co base electrode and permalloy ($\text{Ni}_{80}\text{Fe}_{20}$) counter electrode, but differing barrier fabrication conditions. The junction conductance has been normalized by junction area, and thus, provides a measure of the barrier transmission coefficient. The graphs are ordered such that the parameter R^* area (inverse unit-area conductivity) decreases from the top graph. Nominal thicknesses of the Al layer as well as oxidation times are indicated in the insets with each pair of curves. Due to the exponential dependence of tunneling conductance on barrier thickness and height, R^* area of these samples vary by more than a factor of 20 even though the barriers are very similar. It is evident from this set of curves that little if any change in the bias dependence of tunneling resistance and MR is incurred by changing the barrier transmission, within the range of our data.

Figure 3(b) shows the same representative bias dependence for a series of junctions with different electrode material combinations. Although the material combinations are far from complete, the data seem to suggest a correlation between the bias dependence of the junction resistance with the material of the negatively biased electrode. Particularly, when the Co electrode is negatively biased there is a dip in the resistance curve at about 150 mV, and when $\text{Ni}_{80}\text{Fe}_{20}$ is negatively biased this feature is not present. This observation is consistent with the band-structure effect. Since the tunneling current comes mostly from electrons near the Fermi level of the positive electrode, which are closest in energy to the barrier top, variation in their tunneling probability as a function of bias is a mapping of the negative electrode's density of states above its Fermi level. Differences in the electrode-barrier interface cannot be ruled out as another possible cause of this correlation. The bias dependence of the MR ratio, however, does not vary as much as the resistance itself. Although the maximum MR ratio changes from 12% to 28%, the bias voltage needed to suppress the MR to half of its maximum value within each junction falls within the narrow range of 220–230 mV. We have not identified any correlation between electrode material and variations in the half-

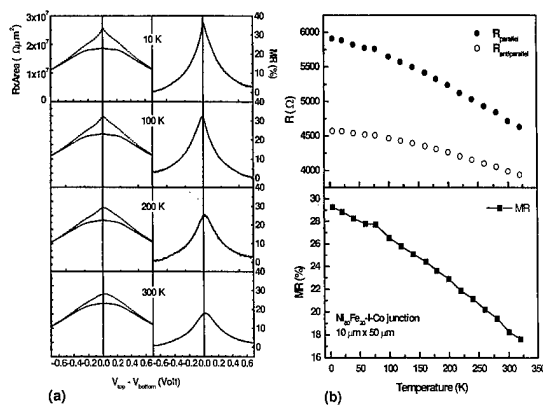

FIG. 4. (a) Bias dependence of R and MR of one MTJ at reduced temperatures. Plots follow the same convention used in Figs. 3(a) and 3(b). (b) Junction resistance and MR plotted as a function of temperature.

maximum bias voltage or the slight asymmetry in the MR curves. This surprisingly “universal” behavior is difficult to understand considering the close relationship between the spin polarization of the material and the MR. Since all these measurements are carried out at room temperature, the underlying mechanism should have a correspondingly high-energy scale. This is also indicated by the size of half-maximum bias.

We have also measured the bias dependence of MTJs at reduced temperature. The results are summarized in Fig. 4(a). As the samples are cooled from room temperature, a cusplike peak gradually develops at zero bias. This peak is limited within about ± 100 mV, and is much more pronounced in the antiparallel configuration than in parallel case. This zero-bias peak and the difference in peak height for the two magnetic configurations account for most of the increase in both junction resistance and MR at zero bias, which are plotted in the Fig. 4(b). This cusplike peak has been attributed to magnon excitations at the electrode-barrier interface by Zhang *et al.*¹² This theory has predicted some significant characteristics of the zero-bias peak, such as the cusplike shape and the size difference in the two magnetic configurations. We have not been able to distinguish the predicted $T \log T$ functional form of the temperature dependence of the zero-bias resistance from other possibilities. Aside from the zero-bias peak just discussed, the general bias dependence at higher voltage ranges does not change significantly with temperature.

Figure 5 compares our results with those of Meservey and Tedrow. The horizontal position of the points shows the MR values calculated using formula (1). The vertical positions then indicate the highest MR measured in each group of junctions, at room temperature (filled) and liquid-helium temperature (open). The room-temperature MR (black square) is generally 70%–90% of the predicted value, while low-temperature values have less dependence on electrode material and, for low P materials, are much higher than predicted. The reduction of MR at room temperature could come from the smearing of the Fermi surface or from thermally activated conduction that is spin independent. Another

FIG. 5. Maximum MR values measured for MTJs with several electrode material combinations vs predicted values using the two-current model and spin-polarization factors measured in FM-I-S tunneling experiments. Room-temperature data are plotted as filled circles and liquid-helium temperature data as open circles, and solid lines indicate the prediction.

factor to be concerned is the loss of magnetization at elevated temperature, i.e., magnon excitation in the material or at the interface. Although the low-temperature data are not as extensive as those at room temperature, the continuity in temperature dependence and consistency in different junctions clearly precludes defects as the reason for the higher MR observed. Whether this discrepancy is due to some subtle difference between FM-I-S and FM-I-FM tunneling or other spin-dependent effects beyond the two-current model is unknown. It is also possible that the polarization values determined 20 years ago may need to be refined.

Finite bias spin dependent tunneling: A nonequilibrium Green's function approach

Xindong Wang^{a)}

Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37831-6114

The nonequilibrium Green's function theory is applied to a model spin dependent tunneling system at finite bias. In the limit of zero bias, the present result agrees with that of Landauer's formula. For finite bias, it is found that as the bias increases, the magnetoresistance ratio decreases. © 1998 American Institute of Physics. [S0021-8979(98)28811-6]

I. INTRODUCTION

Spin dependent tunneling has attracted ever growing attention due to its vast potential applications. It was recently reported by Marley and Parkin¹ that the magnetoresistance ratio (MR) decreases as the voltage bias increases. The MR is defined here to be $R_{\uparrow\downarrow} - R_{\uparrow\uparrow} / R_{\uparrow\uparrow} + R_{\uparrow\downarrow}$, where $R_{\uparrow\uparrow}$ is the resistance of the magnetic-metal-insulator-magnetic-metal tunnel junction when the magnetizations on both sides of the junction are parallel, and $R_{\uparrow\downarrow}$ is the resistance of the tunnel junction when the magnetizations are antiparallel to each other. In this article, the nonequilibrium Green's function approach² is applied to a model for finite bias spin dependent tunneling. In the zero-bias limit, the present result agrees with Landauer's formula.² It is found that the observed bias dependence of the MR can be explained within a simple model without evoking more complicated mechanisms.

In the next section, a brief derivation of the formalism based on the nonequilibrium Green's function theory is presented. The formalism is applied to a simplified model for finite bias spin dependent tunneling and numerical results are presented.

II. NONEQUILIBRIUM GREEN'S FUNCTION APPROACH TO TUNNELING

In order to make clear the notation used in this article, we will outline the main results of nonequilibrium Green's function theory here. A detailed exposition of the theory can be found in Ref. 2. The three Green's functions used in this article are the correlation function $G^n(\mathbf{r}, \mathbf{r}'; t, t')$, the retarded Green's function $G^r(\mathbf{r}, \mathbf{r}'; t, t')$, and the advanced Green's function $G^a(\mathbf{r}, \mathbf{r}'; t, t')$. They are defined as

$$G^n(\mathbf{r}, \mathbf{r}'; t, t') = i \langle \Psi^\dagger(\mathbf{r}', t') \Psi(\mathbf{r}, t) \rangle, \quad (1)$$

$$G^r(\mathbf{r}, \mathbf{r}'; t, t') = -i \theta(t - t') \langle \{ \Psi(\mathbf{r}, t), \Psi^\dagger(\mathbf{r}', t') \}_+ \rangle, \quad (2)$$

and

$$G^a(\mathbf{r}, \mathbf{r}'; t, t') = i \theta(t' - t) \langle \{ \Psi(\mathbf{r}, t), \Psi^\dagger(\mathbf{r}', t') \}_+ \rangle, \quad (3)$$

where $\hbar = 1$ is adopted throughout this article. Since only steady states are considered in this article, the time depen-

dence of all the Green's functions is just on $t - t'$. We will only need to work with their time Fourier transformations defined as

$$G(\omega) = \frac{1}{2\pi} \int dt G(t) \exp(i\omega t).$$

The retarded (advanced) Green's function satisfies

$$[\omega - T - V - \Sigma^{r(a)}(\omega)] G^{r(a)}(\omega) = \mathbf{I}, \quad (4)$$

where the $\Sigma^{r(a)}$ is the self-energy operator and $\Sigma^a = (\Sigma^r)^\dagger$.

For steady state, the correlation function G^n is related to the other two Green's functions as

$$G^n = G^r \Sigma^n G^a, \quad (5)$$

where Σ^n is the self energy for G^n .

For fermions in equilibrium, Σ^n is related to Σ^r through

$$\Sigma^n = -2if(\omega)\text{Im}(\Sigma^r), \quad (6)$$

where $f(\omega)$ is the Fermi-Dirac distribution function.

For the tunneling devices to be modeled in this article, the system is separated into three regions, left reservoir (infinite lead), device region, and right reservoir (infinite lead). In the reservoirs, quasithermal equilibrium is assumed so that we have $f_L(\omega)$ and $f_R(\omega)$ for the left and right reservoir, respectively. Accordingly, Σ^n is decomposed into three parts:

$$\Sigma^n = \Sigma_L^n + \Sigma_R^n + \Sigma_D^n, \quad (7)$$

where locality of the three parts are assumed so that

$$\Sigma_{L(R)}^n(\omega) = -2if_{L(R)}(\omega)\text{Im}[\Sigma^r(\omega)], \quad (8)$$

and Σ_D^n originates in the dissipative processes within the device region. Since in the two-probe setup, the reservoir is taken to be the infinite lead with infinitesimal $\text{Im} \Sigma^r = -\eta < 0$, we have

$$\Sigma_{L(R)}^n = 2i\eta f_{L(R)}(\omega) \theta_{L(R)}(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') \quad (9)$$

with the limit $\eta \rightarrow 0^+$ to be taken last. Here $\theta_{L(R)}(\mathbf{r})$ is a step function which is one when \mathbf{r} is inside the left(right) reservoir and zero otherwise.

Once G^n is known, the tunneling current density is

$$\mathbf{J} = -\frac{e}{m} \int \frac{d\omega}{2\pi} \lim_{\mathbf{r}' \rightarrow \mathbf{r}} \nabla G^n(\mathbf{r}, \mathbf{r}'; \omega). \quad (10)$$

In the following, we will adopt Rydberg units in which the electron mass, m , is 1/2. For a laterally uniform system,

^{a)}Electronic mail: yxw@ornl.gov

the following two-dimensional Fourier transformation simplifies the problem to an effective one-dimensional problem

$$G(\Sigma)(\mathbf{r}, \mathbf{r}') = \frac{1}{(2\pi)^2} \int d^2\mathbf{q} e^{i\mathbf{q} \cdot (\mathbf{r} - \mathbf{r}')} G(\Sigma)(z, z'; \omega). \quad (11)$$

Substituting these Fourier transformations into Eq. (4), we have

$$\left(\frac{d^2}{dz^2} + \omega - q^2 - V(z) \right) G_q^{r(a)}(z, z'; \omega) - \int dz_1 \Sigma_q^{r(a)}(z, z_1; \omega) G_q^{r(a)}(z_1, z'; \omega) = \delta(z - z'). \quad (12)$$

From Eq. (5), we have

$$G_q^n(z, z'; \omega) = \int dz_1 \int dz_2 G_q^r(z, z_1; \omega) \Sigma_q^n(z_1, z_2; \omega) G_q^a(z_2, z'; \omega). \quad (13)$$

Let the device region be within $[Z_L, Z_R]$, and

$$V(z) = V_L \quad \text{when } z < Z_L, \quad (14)$$

$$V(z) = V_R \quad \text{when } z > Z_R. \quad (15)$$

Let us further assume that

$$\Sigma(z, z') = \delta(z - z') \Sigma(z) \quad (16)$$

for all Σ .

With this local self energy, the retarded and advanced Green's functions have simple forms as given below. Define the following function:

$$\left(\frac{d^2}{dz^2} + \omega - q^2 - V(z) - \Sigma_q^\pm(z; \omega) \right) \psi_q^\pm(z; \omega) = 0 \quad (17)$$

with the following boundary conditions:

$$\psi_q^+(z; \omega) = \exp(ik_R z) \quad \text{when } z > Z_R \quad (18)$$

and

$$\psi_q^-(z; \omega) = \exp(-ik_L z) \quad \text{when } z < Z_L \quad (19)$$

with $k_{R(L)}^2 = \omega - q^2 - V_{R(L)}$.

Then we have for the retarded Green's function,

$$G_q^r(z, z'; \omega) = \frac{\psi_q^+(z_{>}; \omega) \psi_q^-(z_{<}; \omega)}{W(\psi^+, \psi^-)}, \quad (20)$$

and for the advanced Green's function,

$$G_q^a(z, z'; \omega) = \frac{\psi_q^+(z_{>}; \omega)^* \psi_q^-(z_{<}; \omega)^*}{W(\psi^+, \psi^-)^*}, \quad (21)$$

where $z_{>(<)}$ is the larger(smaller) argument of z and z' and the wronskian is

$$W(\psi^+, \psi^-) \equiv \frac{d\psi^+}{dz} \psi^- - \frac{d\psi^-}{dz} \psi^+ = \text{constant}.$$

Substituting Eq. (20), Eq. (21) into Eq. (13) and using the locality assumptions in Eq. (16), and taking the limit of $\eta \rightarrow 0^+$, we have for z and z' within $[Z_L, Z_R]$,

$$G_q^n(z, z'; \omega) = C_q^L(z, z'; \omega) f_L(\omega) + C_q^R(z, z'; \omega) f_R(\omega) + \int_{Z_L}^{Z_R} dz_1 G_{q^r}(z, z_1; \omega) \Sigma_q^n(z_1, z'; \omega) \times G_q^a(z_1, z'; \omega), \quad (22)$$

where

$$C_q^L(z, z'; \omega) = i \frac{\psi_q^+(z; \omega) (\psi_q^+(z'; \omega))^*}{|W(\psi^+, \psi^-)|^2} 2k_L \theta(k_L^2) \quad (23)$$

and

$$C_q^R(z, z'; \omega) = i \frac{\psi_q^-(z; \omega) (\psi_q^-(z'; \omega))^*}{|W(\psi^+, \psi^-)|^2} 2k_R \theta(k_R^2). \quad (24)$$

Here $\theta(x)$ is the step function which is one when $x > 0$ and zero otherwise, and k_L and k_R are real and are defined in Eqs. (18) and (19), respectively. Note that from the factor $2k_{L(R)} \theta(k_{L(R)}^2)$ comes the following limit [cf. Eq. (16)]:

$$\lim_{\eta \rightarrow 0^+} 2\eta \int_{-\infty(Z_R)}^{Z_L(\infty)} dz |\psi_q^{-(+)}(z; \omega + i\eta)|^2. \quad (25)$$

If the dissipation within the device can be neglected, we have the ballistic current density for channel \mathbf{q} (note that $m = 1/2$)

$$I_q(\omega) = -2e \lim_{z' \rightarrow z} \frac{d}{dz} G_q^n(z, z'; \omega), \quad (26)$$

which can be evaluated at Z_L or Z_R to be

$$I_q(\omega) = \frac{4ek_L k_R}{|W(\psi^+, \psi^-)|^2} \theta(k_L^2) \theta(k_R^2) [f_L(\omega) - f_R(\omega)]. \quad (27)$$

Since we have for ψ^+ in the region $z < Z_L$ the following,

$$\psi_q^+(z) = \frac{1}{t_q^+(\omega)} (\exp(ik_L z) + r_q^+(\omega) \exp(-ik_L z)) \quad \text{for } z < Z_L, \quad (28)$$

we have

$$W(\psi^+, \psi^-) = \frac{2ik_L}{t_q^+(\omega)}. \quad (29)$$

Alternatively, we can write the Wronskians in terms of k_R ,

$$W(\psi^+, \psi^-) = \frac{-2ik_R}{t_q^-(\omega)}. \quad (30)$$

So the current density for channel \mathbf{q} is

$$I_q(\omega) = e(1 - R_q) [f_L(\omega) - f_R(\omega)] \theta(k_R^2) \theta(k_L^2), \quad (31)$$

where

$$R_q = |r_q^+(\omega)|^2 = |r_q^-(\omega)|^2. \quad (32)$$

And the total current density is

$$I = \frac{1}{(2\pi)^3} \int d\mathbf{q} d\omega I_q(\omega). \quad (33)$$

In the limit of zero bias, we have the two-probe Landauer formula.² Equation (31) can be viewed as a generalized Landauer formula at finite bias.

III. APPLICATION TO FINITE BIAS SPIN DEPENDENT TUNNELING

For finite bias spin dependent tunneling, the following simplified model is used in this article: Let the bias be $U = \mu_L - \mu_R$, where $\mu_{L(R)}$ is the chemical potential in the left(right) reservoir. Assume the barrier for both spin components of the electrons is V_b and the exchange splitting for the magnetic metal is Δ_{ex} . Then when the magnetizations are parallel to each other, the following tunneling potential is used:

$$\begin{aligned} V_L^\sigma &= -\frac{\sigma}{2} \Delta_{ex} + U, \\ V_R^\sigma &= -\frac{\sigma}{2} \Delta_{ex}, \end{aligned} \quad (34)$$

$$V(z \in [Z_L, Z_R]) = V_b,$$

and when the magnetizations are antiparallel to each other, the following tunneling potential is used:

$$\begin{aligned} V_L^\sigma &= -\frac{\sigma}{2} \Delta_{ex} + U, \\ V_R^\sigma &= +\frac{\sigma}{2} \Delta_{ex}, \end{aligned} \quad (35)$$

$$V(z \in [Z_L, Z_R]) = V_b,$$

where $\sigma = \pm$ is the spin index.

For $V_b = 1.0$ Ryd, $\Delta_{ex} = 0.2$ Ryd, $\mu_R = 0.3$ Ryd, and $Z_R - Z_L = 5.0$ a.u., the MR versus V_b is shown in Fig. 1. It is clear that MR decreases as the bias increases. However, it is surprising that for large bias, MR even changes sign (not

FIG. 1. MR vs bias for $V_b = 1.0$ Ryd, $\Delta_{ex} = 0.2$ Ryd, $\mu_R = 0.3$ Ryd, and $Z_R - Z_L = 5.0$ a.u.

shown in Fig. 1). To understand the MR decrease as the bias increases in our model, we note that as the bias increases, the effect of the exchange splitting is relatively decreased. Whether this is an artifact due to the oversimplified model used here will have to be resolved in the future.

Spin-dependent tunneling in epitaxial systems: Band dependence of conductance

J. M. MacLaren^{a)}

Department of Physics, Tulane University, New Orleans, Louisiana 70118

W. H. Butler and X.-G. Zhang

Oak Ridge National Laboratory, Oak Ridge, Tennessee 37831-6114

We present first principles based calculations of the tunneling conductance between iron electrodes separated by semiconducting ZnSe. We assume that Fe (100) and ZnSe (100) atomic planes are epitaxed. We find that the conductance depends strongly on the relative alignment of the magnetic moments in the two Fe electrodes. The relative change in conductance increases dramatically as the thickness of the semiconductor increases. We show that this effect is due to the fact that electrons from a particular majority spin band are injected efficiently into the ZnSe from the Fe and also that electrons are ejected efficiently from the ZnSe into this band. Our calculations are based upon the Landauer-Büttiker expression for the conductance which is expressed in terms of the transmission matrix elements. © 1998 American Institute of Physics. Recently, it has been observed¹⁻⁵ that the tunneling current through a FM|S|FM sandwich (where FM represents a ferromagnet and S represents a semiconductor or an insulator) may depend on the relative orientation of the moments in the two ferromagnetic layers. Although most experimental observations of spin-dependent tunneling have involved non-epitaxial systems with uncharacterized or amorphous interlayers, there have been recent observations of large spin-dependent tunneling effects in epitaxial systems.^{4,5} Epitaxial systems have the advantage for a first-principles theoretical study that the nominal physical structure is well defined.

Although many treatments of tunneling⁶⁻⁹ and even of spin-dependent tunneling^{10,11} have been proposed, we suggest that a useful understanding of this phenomenon must be based on a realistic approximation to the electronic structure of the ferromagnets, the nonconducting interlayer and especially the interfaces which separate them. As first steps towards that goal we have calculated the self-consistent electronic structure of epitaxial FM|S|FM sandwiches using first principles techniques and we have used these electronic structures to calculate the tunneling conductance for both parallel and antiparallel alignment of the magnetic moments of the ferromagnetic layers.

Both the self-consistent electronic structures¹² and the techniques for calculating the tunneling conductance^{13,14} have been described previously. We have considered the case in which the ferromagnetic layers consist of bcc Fe with (100) atomic planes parallel to the interfaces and the semiconducting layer consists of (100) atomic planes of ZnSe epitaxed to the Fe. For this case we showed¹⁴ that for reasonably thick films the conductance is much larger in the majority channel for parallel alignment of the moments than for the minority moment for the same alignment and that it is also much larger than the conductance of either of the chan-

nels for antiparallel alignment. This leads to a large magnetoconductance which increases with increasing film thickness.

In this article we point out that the tunneling conductance may vary dramatically from band to band. The contribution from one particular majority channel band at the Fe Fermi energy is responsible for the large majority conductance and ultimately for the large calculated change in conductance when the alignment of the moments in the two magnetic layers is changed. The band in question was singled out previously by Stearns.¹⁰

The Layer Korringa Kohn Rostoker (LKKR) technique¹⁵ was used to solve the equations of density functional theory in the local density approximation. The LKKR technique assumes that the system consists of atoms that are arranged in periodic layers, but it allows the treatment of systems which are not periodic in the direction perpendicular to these layers. We took advantage of this feature to calculate the self-consistent electronic structure of 9 atomic layers of ZnSe embedded in bcc iron.¹² The calculations showed a large peak in the minority Fermi energy density of states localized on the interfacial Fe layer, and the formation of a dipole layer at the interface which correctly places the Fermi energy of the semiconductor interlayer relative to that of the bulk iron.

We also calculated the tunneling conductance as a function of the thickness of the ZnSe using between 9 and 33 layers of Zn and Se. The tunneling conductance was calculated using the Landauer-Büttiker formalism¹⁶ implemented for Bloch electrons.^{13,14} In this formalism the conductance is expressed as a sum of the transmission probability over "channels." In this case the channels are the Bloch states which are enumerated by k_{\parallel} , the component of the momentum in the plane of the layers (taken to be the $x-y$ plane), by a propagation index, \pm , which indicates the direction of propagation of the Bloch wave perpendicular to the layers, and by a band index which distinguishes between the bands for a given value of k_{\parallel} . Thus the conductance for a given

^{a)}Electronic mail: james@maclaren.phy.tulane.edu

FIG. 1. Dependence of current on k_x for fixed $k_y \approx 0$ for majority electrons for the case of parallel alignment of the moments in the two ferromagnetic layers. The numbers near each curve indicate the number of Zn and Se layers in the interlayer.

FIG. 2. Dependence of current on k_x for fixed $k_y \approx 0$ for minority electrons for the case of parallel alignment of the moments in the two ferromagnetic layers.

spin channel is given by $G = (e^2/h) \sum_{k_{\parallel}, i, j} T^{i+, j+}(k_{\parallel})$, where $T^{i+, j+}(k_{\parallel})$ is the transmission probability for a right going Bloch state $i+$ with the given value of k_{\parallel} on the left hand side of the semiconductor to be transmitted into the right going Bloch state $j+$ with the same value of k_{\parallel} on the right hand side of the barrier. In our calculations k_{\parallel} is conserved in the tunneling processes because of the assumed two-dimensional periodicity of the system.

Three-dimensional plots which show the conductance as a function of k_{\parallel} over the entire two-dimensional Brillouin zone for 9 and for 33 layers of Zn and Se were presented in Ref. 14. In Fig. 1 we show plots of the conductance along a line in the two-dimensional zone which runs approximately along the line from $\bar{\Gamma}$ to \bar{H} . As the thickness increases it can be seen that the current becomes more strongly peaked near $k_x = 0$. Superposed on this general behavior is a thickness dependent structure of the current as a function of k_x . The wavelength of at least some of this structure decreases as the thickness of the interlayer increases. Little of the structure is present in the current calculated for a simple spatially uniform barrier. The origin of this structure lies partly in the band structure of the Fe since there can only be transmission for those values of k_x for which there are bands to inject the electrons into the ZnSe and bands to receive the electrons that are ejected from the ZnSe. We suggest, however, that most of the structure, especially that part that depends on the interlayer thickness arises, from the “interference” of electron waves reflected off of the interfaces between the Fe and ZnSe.

Similar “interference” effects can be seen in the minority current as a function of k_{\parallel} which is displayed in Fig. 2. The major differences between the majority and minority transmission probabilities are the smaller maximum values in the minority channel and the pronounced minimum near $k_{\parallel} = 0$. The pronounced minimum near $k_{\parallel} = 0$ for the minority and the smaller minimum near $k_{\parallel} = 0$ for the majority seem to be related to the Fe bands since similar structure is seen in the current calculated for a simple spatially constant barrier.

The suggestion of “interference” effects in the tunneling conductance may seem strange since tunneling electrons are generally perceived to be tunneling through a “barrier.” It should be realized however that the ZnSe layers do not present a classical barrier to electrons, only a quantum mechanical one. Electrons at the Fermi energy find all of space except a small region near the interstitial points classically accessible, i.e., $E_F > V(\mathbf{r})$. If the electrons were classical particles almost all of them would be transmitted. Although Bloch waves cannot propagate at the Fermi energy in the ZnSe because destructive interference leads to a band gap, this same interference leads to the rapid changes in transmission probability with k_x that is seen in Figs. 1 and 2.

In order to gain a better understanding of the difference between the conductance in the majority channel and the minority channel and to better understand the change in conductance when the moment alignment is switched from parallel to antiparallel, we calculated the density of states (DOS)

FIG. 3. Density of states for majority electrons incident from the left for the case of aligned moments. The DOS is shown for each majority band at the Fermi energy for $k_{\parallel} = 0$. This corresponds to bands in the three-dimensional zone that intersect the Fermi energy along the line $\bar{\Gamma} \rightarrow \bar{H}$. The sawtooth shape of the DOS in the ZnSe interlayer is due to alternate layers being Zn and Se.

FIG. 4. Density of states at $k_{\parallel}=0$ for majority electrons incident from the left for the case of antialigned moments.

for Bloch electrons incident on the semiconducting interlayer. Imagine calculating the density of states of Bloch electrons in Fe with a given value of k_{\parallel} . Let us further restrict the DOS to those Bloch electrons with a given k_{\parallel} and whose z component of Fermi velocity is greater than zero, i.e., electrons traveling from left to right. Now imagine that we insert the ZnSe interlayer into the Fe. Most of the Bloch electrons will be reflected, but a few will penetrate into the semiconductor where we expect the DOS to decay exponentially and a few will be transmitted. This DOS is shown in Fig. 3 for each band in Fe at the Fermi energy with $k_{\parallel}=0$.

The most salient feature of Fig. 3 is the relatively large DOS for band 3 inside the semiconductor. The electrons from this particular Bloch wave are able to penetrate easily into the semiconductor. They also exit the semiconductor easily when the moments are aligned. However, they are not so easily ejected when the moments are antialigned as is shown in Fig. 4. There is a surprising variability in the rate of decay of the wave function within the ZnSe interlayer. After about 20 atomic layers only electrons from band 3 of the Fe contribute significantly to the DOS. The DOS from band 3 decays only about 1/3 as fast as the other majority states. If the decay for band 3 is fit to $e^{-z/\ell}$, ℓ is approximately 9 Å.

Figure 5 shows the DOS for minority electrons incident from the left. The DOS for all of the minority bands is seen to decay rapidly to zero. The decay length for these states is approximately the same as for the majority electrons other than band 3.

The distinguishing characteristic of majority band 3 compared to the other bands at the Fermi energy is that it has much more s and p character. This particular band was described by Stearns¹⁰ as "itinerant" d . Stearns also argued that this band would be important for spin-dependent tunneling.

FIG. 5. Density of states at $k_{\parallel}=0$ for minority electrons incident from the left for the case of aligned moments.

Anomalous behavior of temperature and bias-voltage dependence of tunnel-type giant magnetoresistance in insulating granular systems

S. Mitani,^{a)} K. Takanashi, K. Yakushiji, and H. Fujimori
Institute for Materials Research, Tohoku University, Sendai 980-77, Japan

We have investigated temperature and bias-voltage dependence of tunnel-type giant magnetoresistance (MR) in Co–Al–O insulating granular films. A remarkable enhancement of MR which is larger than the theoretical value by a simple model is observed for Co–Al–O granular films at low temperatures, and it steeply decreases with increasing temperature. On the other hand, the MR does not decrease with increasing bias voltage although the resistivity decreases by a few orders of magnitude. Furthermore, it has been found that the effect of temperature is definitely different from that of bias voltage. The anomalous behavior is in contrast to that of macroscopic tunnel junctions, suggesting the significant effect of Coulomb blockade in granular systems. © 1998 American Institute of Physics. [S0021-8979(98)28911-0]

I. INTRODUCTION

Spin-dependent transport phenomena in artificial nanostructures have attracted much attention in the fields of physics and electronics.¹ The tunnel-type giant magnetoresistance (GMR) in insulating granular systems, e.g., Co–Al–O sputtered films, is one of such novel phenomena.^{2,3} The insulating granular systems consist of magnetic metal granules (e.g., Co) and nonmagnetic insulating matrix (e.g., Al oxide), and the magnetoresistance (MR) is caused by the tunneling current between magnetic metal granules depending on their magnetization directions. In a previous article, we reported a preliminary result on the enhancement of MR at low temperatures in Co–Al–O and Fe–Al–O granular films.⁴ This article provides further investigations including the anomalous behavior of temperature and bias-voltage dependence of MR in Co–Al–O granular films.

II. EXPERIMENTAL PROCEDURE

Co–Al–O granular films (1 to 2 μm in thickness) were prepared on glass substrates using a reactive-sputtering technique with mixed gas of Ar+O₂. Details of the sample preparation and the structural characterization were described previously in our articles.^{3,5} Electrical resistivity (ρ) were measured using a dc four-terminal method, as a function of the temperature between 2 and 300 K, and of the applied magnetic field up to 12 kOe. Magnetization curves were measured by a superconducting quantum interference device (SQUID) magnetometer with the field applied up to 50 kOe. On the basis of the proportional relation between MR and square of the normalized magnetization,³ i.e., $\Delta\rho/\rho_{\text{max}} \propto (M/M_s)^2$, it was confirmed that the MR at 12 kOe almost reaches the saturated state. In case that MR did not saturate at 12 kOe, the saturation values of MR were extrapolated using $\Delta\rho/\rho_{\text{max}} \propto (M/M_s)^2$.

The bias-voltage (V_b) dependence of MR was measured at 12 kOe and 4.2 K in the current-perpendicular-to-plane (CPP) geometry where the Co–Al–O granular films were

sandwiched with upper and lower electrodes of Au–Cr alloy, as shown in Fig. 1. The source dc current was controlled in order to adjust V_b between voltage electrodes to a constant value in the accuracy of less than 0.01% because the resistivity varies drastically via the change of the bias-voltage V_b .

III. RESULTS AND DISCUSSION

Figure 2 shows the temperature dependence of MR for the Co–Al–O films with different compositions: Co₅₄Al₂₁O₂₅, Co₅₂Al₂₀O₂₈, and Co₃₆Al₂₂O₄₂. It is clearly seen that the MR is remarkably enhanced at low temperatures. The MR reaches up to 24% around 2 K for the Co₃₆Al₂₂O₄₂ film, and the MR decreases dramatically with increasing temperature. The dashed line of $P_{\text{Co}}^2/(1+P_{\text{Co}}^2)$ shown in Fig. 2 is the magnitude of MR calculated theoretically using a simple model of tunneling transport,⁶ where P_{Co} is the spin polarization of conduction electrons in Co granules. $P_{\text{Co}}^2/(1+P_{\text{Co}}^2)$ is calculated to be about 10% using the value of P_{Co} (34%) obtained by means of tunnel spectroscopy experiments.⁷ This simple model was originally proposed for MR effect in ferromagnetic tunnel junctions and gave the result of $\text{MR} = 2P^2/(1+P^2)$, where P is the

FIG. 1. Schematic illustration of a Co–Al–O film for the measurement in current-perpendicular-to-plane (CPP) geometry.

FIG. 2. Temperature dependence of MR for $\text{Co}_{54}\text{Al}_{21}\text{O}_{25}$, $\text{Co}_{52}\text{Al}_{20}\text{O}_{28}$, and $\text{Co}_{36}\text{Al}_{22}\text{O}_{42}$ films. $P^2/(1+P^2)$ is the theoretical value of MR in Co-based insulating granular systems by a simple model. The values of C/k_B are also shown for the films (see the text).

spin polarization for ferromagnetic metal.⁶ The factor of 2 is just due to the difference between the random magnetization alignment in granular systems and antiparallel magnetization alignment in ferromagnetic tunnel junctions. The magnitudes of MR reported so far for ferromagnetic tunnel junctions with a macroscopic size were always smaller than the theoretical value of $2P^2/(1+P^2)$. For insulating granular films, however, Fig. 1 indicates that the MR can be much larger than the theoretical value.

Figures 3(a) and 3(b) show ρ and MR, respectively, as functions of bias-voltage V_b for the $\text{Co}_{36}\text{Al}_{22}\text{O}_{42}$ film. The magnitude of MR is 19%, and it is almost constant in the range of $V_b=0$ to 600 mV although ρ decreases by three orders of magnitude. For the results of the temperature and bias-voltage dependence of MR, we would like to emphasize the two following points which are characteristic of granular systems: The first is that the MR as a function of bias voltage is independent of the dramatic change in ρ . This is in clear contrast to the case of ferromagnetic tunnel junctions with a macroscopic size, where both MR and ρ decrease gradually with increasing bias voltage.⁸ The second point is the difference between the temperature and bias-voltage dependence of MR. We can estimate the number of Co granules aligned between the upper and lower electrodes, using the mean diameter of granules (20–30 Å),⁵ the mean thickness of insulating barriers (~ 10 Å),⁵ and the film thickness (1.0 μm), and it is calculated to be 250–300. Therefore, the applied bias voltage per one microjunction between two neighboring Co granules is estimated to be approximately 2 mV at $V_b=600$ mV. The 2 mV corresponds to 23 K in temperature. Therefore, it is shown that the MR does not decrease up to the bias voltage corresponding to 23 K. On the other hand, as

FIG. 3. Bias-voltage (V_b) dependence of ρ and MR for a $\text{Co}_{36}\text{Al}_{22}\text{O}_{42}$ film at 4.2 K; (a) ρ and (b) MR.

shown in Fig. 2, MR decreases with increasing temperature up to 23 K. This indicates that the effect of temperature is different from that of bias voltage. This is also in clear contrast to the case of ferromagnetic tunnel junctions with a macroscopic size. The effect of bias voltage is not so different from that of temperature.⁹

We will discuss the above-mentioned remarkable features of MR in granular systems in relation to the effect of Coulomb blockade. Figure 4 shows $\log \rho$ as a function of $T^{-1/2}$ for $\text{Co}_{54}\text{Al}_{21}\text{O}_{25}$, $\text{Co}_{52}\text{Al}_{20}\text{O}_{28}$, and $\text{Co}_{36}\text{Al}_{22}\text{O}_{42}$ films. The linear relationship is seen, showing $\log \rho = \alpha T^{-1/2}$ (α : constant). The characteristic behavior of $\log \rho = \alpha T^{-1/2}$ appears due to the combination of (i) the tunneling effect of electrons between metallic granules through intergranular insulating barriers and (ii) the electrical charging effect of metallic granules (Coulomb blockade). The constant α is expressed as

FIG. 4. $\log \rho$ as a function of $T^{-1/2}$ for $\text{Co}_{54}\text{Al}_{21}\text{O}_{25}$, $\text{Co}_{52}\text{Al}_{20}\text{O}_{28}$, and $\text{Co}_{36}\text{Al}_{22}\text{O}_{42}$ films.

$$\alpha = 2(C/k_B)^{1/2}, \quad (1)$$

where the constant C is called tunnel-activation energy¹⁰ and k_B is Boltzmann constant. C is given by¹⁰

$$C = (2m\phi)^{1/2}(h/2\pi)sE_c, \quad (2)$$

where m is the effective electron mass, ϕ is the effective potential height of insulating barrier, h is Planck's constant, s is the barrier thickness, and E_c is the charging energy of a metallic granule. The coefficient between C and E_c , i.e., $(2m\phi)^{1/2}/(h/2\pi)s$, can be determined to be the order of 1, using $m = 9.11 \times 10^{-28}$ g (free electron's mass), $\phi \sim 1$ eV (the order of potential height of Al_2O_3), and $s \sim 10$ Å.^{5,10} Therefore, C is considered to be roughly equal to E_c . The magnitudes of C/k_B obtained from the experiments are shown in Fig. 2, i.e., 30, 80, and 420 K for the $\text{Co}_{54}\text{Al}_{21}\text{O}_{25}$, $\text{Co}_{52}\text{Al}_{20}\text{O}_{28}$, and $\text{Co}_{36}\text{Al}_{22}\text{O}_{42}$ films, respectively. The $\text{Co}_{36}\text{Al}_{22}\text{O}_{42}$ film has the largest charging energy, and hence it may show the largest effect associated with Coulomb blockade. The $\text{Co}_{36}\text{Al}_{22}\text{O}_{42}$ film shows the largest MR effect, and we find in Fig. 2 that the MR is larger as C/k_B is larger. Furthermore, the enhancement of MR for each film appears below the temperature which corresponds approximately to the charging energy of granules. This suggests that the enhancement of MR appears in relation to the Coulomb blockade effect. Ono *et al.* reported enhanced MR associated with Coulomb blockade in microfabricated ferromagnetic tunnel junctions.¹¹

Recently, Takahashi and Maekawa calculated temperature and bias-voltage dependence of MR for a ferromagnetic double-junction system with a small island electrode in Coulomb blockade regime.¹² The behavior of temperature and bias-voltage dependence of MR in the theoretical work is similar to our experimental results for granular systems. It is suggested that the theory in Coulomb blockade regime would elucidate the origin of the difference of the temperature and bias-voltage dependence in granular systems.

IV. CONCLUSION

The remarkable enhancement of MR which is larger than the theoretical values, $P^2/(1+P^2)$, is observed for Co-Al-O granular films at low temperatures, and it steeply decreases with increasing temperature. On the other hand, the MR does not decrease with increasing bias voltage although ρ decreases by a few orders of magnitude. Furthermore, it has been found that the effect of temperature is definitely different from that of bias voltage. The anomalous behavior is in contrast to that of macroscopic tunnel junctions, suggesting the significant effect of Coulomb blockade in granular systems.

High perpendicular anisotropy and magneto-optical activities in ordered Co₃Pt alloy films

Y. Yamada,^{a)} W. P. Van Drent, E. N. Abarra, and T. Suzuki

Information Storage Materials Laboratory, Toyota Technological Institute, 2-12-1, Hisakata, Tempaku, Nagoya 468, Japan

The origin of the large perpendicular magnetic anisotropy constant K_u of Co₃Pt alloy thin films is discussed. The films deposited onto Al₂O₃(0001), Al₂O₃(1120), and MgO(111) substrates held at 230–450 °C during deposition exhibit K_u of the order of 10^7 erg/cm³ at room temperature. While the one dimensional long range order parameter S estimated by x-ray diffraction is very consistent with the development of the perpendicular magnetic anisotropy in the films deposited at 380–450 °C, very little evidence is found to suggest the correlation between S and K_u for the lower deposition temperature range (230–380 °C). To explain this, a short range ordering is suggested to be responsible for the origin of K_u , similar to the cases in Pt₇₂Co₂₈ alloys. The magneto-optical polar Kerr activity of ordered Co₃Pt film is found to be enhanced for both θ_K and η_K in the photon energy range from 2 to 4 eV. © 1998 American Institute of Physics. [S0021-8979(98)43611-9]

I. INTRODUCTION

Recently, several different workers reported large perpendicular magnetic anisotropy constants K_u on the order of 10^7 erg/cm³ in Co–Pt and Fe–Pt alloy thin films of various composition.^{1–5} The origin of such a high perpendicular magnetic anisotropy has been the subject for many workers. Tyson *et al.*⁶ have shown that the anisotropic distribution of the Co–Co bonds is responsible for the magnetic anisotropy in Co_{1–x}Pt_x alloys ($x \sim 0.7$), similar to the orientational asymmetry in the Fe–Fe, Tb–Tb, and Tb–Fe bonds in amorphous TbFeCo alloy films.⁷ Harp *et al.*⁸ showed the existence of the ordered phase of Co₃Pt alloy films, which had not been in the phase diagram for a long time. However, no magnetic anisotropy of this ordered phase had been reported. Recently, Yamada *et al.*^{1,2} reported for the first time on a large perpendicular anisotropy in Co-rich CoPt alloys, and suggested the possible correlation of the order phase of Co₃Pt with the origin of the magnetic anisotropy. However, the detailed mechanism of the magnetic anisotropy has not been understood. The present article describes a further result of the perpendicular magnetic anisotropy in Co_{1–x}Pt_x ($x \sim 0.2–0.3$) alloy thin films.

II. EXPERIMENT

Co_{1–x}Pt_x ($0 \leq x \leq 0.5$) alloy thin films were deposited onto fused silica, MgO(111), Al₂O₃(0001), and (1120) substrates by electron beam evaporation using separate Co and Pt sources. The detailed deposition condition was described elsewhere.^{5,6} The film thickness was approximately 1000 Å for all cases. Measurements of magnetic properties were carried out by using vibrating sample magnetometer, alternative gradient force magnetometer, and torque magnetometer in

fields up to 20 kOe. The magneto-optical Kerr effect was measured using an ultrawide range Kerr spectrometer in a photon energy range from 1.4 to 6.8 eV.⁹ The measurement was made from the sample surface side.

III. RESULTS AND DISCUSSION

The intrinsic perpendicular anisotropy constant K_u (defined as $K_u = K_\infty + 2\pi M_s^2$, where K_∞ is the torque amplitude as $H \rightarrow \infty$) at different compositions of Co–Pt alloy films was studied. Figure 1 shows the dependence of K_u on film composition at various substrate deposition temperatures T_s . One can see that K_u values of the films deposited onto Al₂O₃(0001) and MgO(111) substrates at $T_s = 400$ °C ex-

FIG. 1. Dependence of the perpendicular anisotropy constant K_u on Pt content.

FIG. 2. Dependence of the perpendicular anisotropy constant K_u on substrate deposition temperature for $\text{Co}_{75}\text{Pt}_{25}$ films.

hibit a maximum at about 25 at % Pt. On the other hand, a very small change of K_u with film composition for the samples deposited at 25 °C and deposited onto fused silica was observed. The maximum values of K_u are 2.1×10^7 and 1.6×10^7 erg/cm³ for $\text{Al}_2\text{O}_3(0001)$ and $\text{MgO}(111)$ substrates, respectively.

Figure 2 shows the dependence of K_u on T_s for 25 at % Pt thin films deposited onto various substrates. The K_u becomes zero at about 500 °C for all the samples. The maximum value of K_u for samples on $\text{Al}_2\text{O}_3(0001)$ is 2.1×10^7 erg/cm³, and those on $\text{Al}_2\text{O}_3(1120)$ and fused silica are 1.2×10^7 and 1.0×10^7 erg/cm³ at room temperature, respectively. It is clearly seen that for all the substrates cases, there is a broad maximum of K_u at $T_s = 250$ – 400 °C for both the Al_2O_3 cases, and 200–300 °C for the fused silica case.

The x-ray diffraction analysis indicates that all these samples deposited onto the Al_2O_3 and MgO substrates exhibit the hcp structure for T_s from the ambient temperature to about 450 °C with the textured (0001) along the film normal. Furthermore, the hcp (0001) superlattice peak is observed for the samples deposited onto $\text{Al}_2\text{O}_3(0001)$, $\text{MgO}(111)$, and $\text{Al}_2\text{O}_3(1120)$ at approximately 380–450 °C.

The one dimensional order parameter S is defined as

$$S = \frac{r_A - F_A}{1 - F_A} \propto \left(\frac{I_{0001}}{I_{0002}} \right)^{1/2},$$

where r_A is the fraction of A sites occupied by A atoms, F_A is the fraction of A atoms in the alloy, I_{0001} and I_{0002} are the integrated intensities of the fundamental peaks and the superlattice peak, respectively. Thus, the one dimensional order parameter S can be estimated by measuring the integrated intensity ratio.¹⁰

Figure 3 shows the dependence of S on T_s . It shows a sharp peak at ~ 400 °C for both the $\text{Al}_2\text{O}_3(0001)$ and (1120) cases, where K_u becomes maximum. This result is consistent with the work by Harp *et al.*⁸

Figure 4 shows the relation between K_u and order pa-

FIG. 3. Dependence of the order parameter S on substrate deposition temperature for $\text{Co}_{75}\text{Pt}_{25}$ films.

rameter S for the thin film deposited onto the $\text{Al}_2\text{O}_3(0001)$ substrate. The numbers close to the data points correspond to T_s . K_u is found to vary linearly with S for T_s between 380 °C and 450 °C, indicating that the ordering is a primary factor governing K_u in this temperature range. One would expect K_u of 4×10^7 erg/cm³ for a perfectly order state. On the other hand, there is no clear correlation between K_u and S for T_s less than 380 °C. This situation is similar to the case of CoPt_3 alloy films.¹¹ Tyson *et al.*⁶ have shown evidence for a directional anisotropy in the number of Co–Co bonds in $\text{Co}_{28}\text{Pt}_{72}$ alloy films by using x-ray absorption fine structure (XAFS). To clarify this matter, an experiment was performed in which case a deposition rate was changed to a lower rate at $T_s = 230$ °C for $\text{Al}_2\text{O}_3(0001)$ substrates. One sample was deposited at 1.6 Å/s, which is the same as all other experiments. The deposition rate for the other sample was lowered to 1/5 of the original. It was found that both K_u

FIG. 4. Relation between K_u and the order parameter S for the films deposited onto $\text{Al}_2\text{O}_3(0001)$. The numbers close to the data points corresponds to T_s .

FIG. 5. A model for the origin of the large K_u ; short range ordering for low T_s (left) and Co_3Pt ordered structure for high T_s (right).

and S increased with lowering a deposition rate ($K_u = 1.3 \times 10^7 - 1.8 \times 10^7 \text{ erg/cm}^3$, $S = 0$ to 0.12). This result seems to support the model put forward by Tyson *et al.*⁶ A model of a short range ordering to account for large K_u is shown in Fig. 5(a). In this model, atomic layers of CoPt_x and CoPt_y are alternately present, as ABAB stacking. The origin of the large perpendicular magnetic anisotropy is believed to result from the anisotropic bonding distribution of Co–Co atoms in the film plane with respect to the film thickness direction, as proposed by Tyson *et al.*⁶ This situation may also be similar to Co/Pt multilayers.

Figure 6 shows the Kerr rotation and ellipticity spectra for $\text{Co}_{75}\text{Pt}_{25}$ alloy thin films deposited onto an $\text{Al}_2\text{O}_3(0001)$ substrate at $T_s = 25^\circ\text{C}$ (disordered) and 400°C (ordered) in a photon energy range from 1.4 to 6.8 eV. The Kerr rotation spectrum, which was obtained by Harp *et al.* for $\text{Co}_{75}\text{Pt}_{25}$ thin film deposited at 375°C ,⁸ is also shown. The spectrum for the sample deposited at 400°C shows slightly larger θ_K and η_K for photon energies less than 4 and 6 eV, respectively. The present result for the ordered structure ($T_s = 400^\circ\text{C}$) does exhibit the peak around 3 eV, consistent with their result.

IV. CONCLUSION

The very large perpendicular magnetic anisotropy constant K_u values are found in $\text{Co}_{75}\text{Pt}_{25}$ alloy thin films deposited at $T_s = 230$ – 450°C . The relation between K_u and the order parameter S is investigated in detail for Co–Pt alloy thin films. When the substrate deposition temperature is high (380 – 450°C), the magnitude of K_u is linearly correlated with S . However, when T_s is not high enough (230 – 380°C), no clear correlation is found. To account for these high K_u values, a short range ordering is suggested for the origin of the large K_u at lower T_s , where the films exhibit a large K_u without ordering. The magneto-optical activities of these

FIG. 6. Magneto-optical spectra for the samples deposited onto $\text{Al}_2\text{O}_3(0001)$ at various T_s .

Co–Pt alloy thin films were measured. The enhancement in Kerr rotation at $\sim 3.0 \text{ eV}$, which is characteristic for Co_3Pt ordered structure, is observed.

Thermopower studies of percolating magnetic metallic nanostructures

X. N. Jing^{a)} and X. Yan^{b)}

Department of Physics, Hong Kong University of Science and Technology,
Clearwater Bay, Kowloon, Hong Kong

We have observed a small and temperature insensitive thermal electric power S as well as a large resistivity following $\rho \sim -\log(T)$ dependence, in percolating magnetic metal-insulator nanocomposites, irrespective to the sign of the carrier. Upon annealing, however, a normal metallic behavior with a linear temperature dependence for both S and ρ was recovered. We propose that the large charging energy of the nanometer sized particles in the percolation conduction channels is responsible for this observation as well as the giant Hall effect or the loss of the effective carrier density in these nanostructures. © 1998 American Institute of Physics. [S0021-8979(98)52211-6]

There is renewed interest in magnetic metal-insulator nanocomposite materials, or magnetic nanostructures, due to the recent discoveries of giant magnetoresistance (5%–10%) when tunneling conduction exists between the adjacent magnetic metal particles,¹ and giant Hall effect (GHE), or a 10 000-fold enhancement of Hall resistivity when the nanometer-sized magnetic metal particles form percolation conduction channels.² GHE cannot be explained via a simple percolation theory that predicts a maximum enhancement factor of ~ 20 (Ref. 3) based on the percolation critical exponent of Hall resistivity $g \sim 0.4$ (Ref. 4) for a 1 μm thick film. From our systematic studies of Ni-rich NiFe–SiO₂ and Fe–SiO₂ nanocomposite films, having carrier dominated by electrons and holes, respectively, a few unique properties were identified near the percolation threshold.^{2,5–8} Namely, the giant enhancement of Hall resistivity exists if and only if there exist a large resistivity (0.1–1 Ωcm) with a temperature dependence following $\rho(T) \sim -\log(T)$, and nanometer-sized particles in the percolating channels,⁵ which are independent of the sign of the conduction carrier. In the following discussion, we use the term “percolating magnetic nanostructure” to refer to a system with the above-mentioned novel properties. Understanding of these properties is limited.⁹ Particularly the apparent dramatic loss of “effective carrier” still lacks an important clue for its origin.^{9,10} A measure of “entropy per carrier,” thermal electric power was chosen to help identify the origin of the carrier loss.¹¹

Percolating (NiFe)_x(SiO₂)_{1-x} and Fe_x(SiO₂)_{1-x} nanostructured films were prepared using a magnetron rf co-sputtering system as described elsewhere.^{2,5,9} Samples used for this work were from the same batch in which giant Hall effect was found. The saturation Hall resistivity are about $-200\ \mu\Omega\text{cm}$ and $+500\ \mu\Omega\text{cm}$ for (NiFe)_x(SiO₂)_{1-x} and Fe_x(SiO₂)_{1-x}, indicating that giant Hall effect exists irrespective to the sign of the conduction carrier. The thickness and the deposition temperatures were 1 and 0.5 μm and 150 and 25 $^{\circ}\text{C}$ for the two systems, respectively. The metal volume fraction x were determined by energy-dispersive

x-ray spectroscopy using a Philips EDAX XL30. For NiFe–(SiO₂), the relative Fe content in NiFe, was determined to be 0.15, 0.14, and 0.14, for $x = 0.58, 0.61$, and 0.63 , respectively.⁵ For annealing, samples were placed in a quartz tube that was evacuated for half an hour and purged six times using high-purity helium gas. The quartz tube was heated at 520 $^{\circ}\text{C}$, and pulled out to room temperature after 1 h.⁵ 520 $^{\circ}\text{C}$ was chosen because from previous studies it is known that the giant Hall effect will disappear to a normal metallic behavior⁵ in a conventional metal-insulator composite system above the percolation threshold.

Thermal electric power (thermopower or TEP) measurements were performed on narrow strips of the sample (typically $12 \times 1.5\text{ mm}$) by using a pulsed heating method.¹² While the resistance was measured using a four-probe technique. Gold wires of $\phi 25\ \mu\text{m}$ were served as both current and voltage leads. Chromel/constantan thermocouple (type E) with diameters of 25 μm , connected in a differential mode, were fixed onto the sample with the thermal contact close to the two voltage electrodes. Resistance and TEP data on the same sample were taken in sequence with the temperature decreasing at a rate controlled at $\sim 3\text{ mK/s}$. A temperature gradient $\Delta T \sim 1\text{--}2\text{ K}$, generated by a small carbon film heater, was applied along the sample. Care was taken to null the offset values by turning the heater on and off periodically. The voltage drop on the sample and that for temperature gradient were obtained by the voltage difference with the heat on and off by using two Keithley 182 nanovoltmeters. For each on or off voltage, 30 repeated readings were averaged after reaching a thermally static state. The absolute thermopower of gold wire was calibrated against a pure lead, and the calibration was in agreement with that in Ref. 12. All the TEP data shown in this article are the absolute thermopower by subtracting off the contribution of the gold wires.

Figure 1 shows TEP S as functions of temperature of (NiFe)_x(SiO₂)_{1-x} films for (a) various volume fraction, $x = 0.58, 0.60, 0.63$, and 1 , and (b) for one percolating sample, $x = 0.58$ for various annealing conditions. All these samples are above the percolation threshold x_c of 0.53 .² Compared with a homogeneous metallic sample, the TEP near the percolation appears to be quite insensitive to the temperature, as is often the case in typical disordered metals.¹³ Since TEP is

FIG. 1. Thermopower as functions of temperature of $(\text{NiFe})_x(\text{SiO}_2)_{1-x}$ films for (a) as-deposited films with different volume fractions and (b) different annealing conditions for $x=0.58$.

a measure of "entropy per carrier," such a temperature insensitive TEP indicates that the entropy of the carrier is determined by another energy scale that is either much larger or much smaller than kT in such a disordered percolating system. Another striking finding is a similar linear temperature dependent TEP for both a pure metallic case ($x=1$) and the percolating samples after annealing, suggesting that neither the thermal power in a two-component composite model¹⁴ nor the percolating geometry alone is sufficient to give rise to a temperature independent TEP. A linear temperature dependent TEP indicates that the electron conduction in the classical percolating system is similar to liquid metals or semimetals where electron states near the Fermi surfaces are nonlocalized despite the disorder.

Shown in Fig. 2 is the temperature dependence of the resistivity (normalized to 79 K), for $x=0.58$ with $T_a=150^\circ\text{C}$, and 520°C , and for $x=1$ (as-deposited). The dashed line is a fit to a $-\log(T)$ dependence. For the as-

FIG. 3. Temperature dependence of thermopower (a) and resistivity (b) for as-deposited $\text{Fe}_x(\text{SiO}_2)_{1-x}$ films.

deposited sample near the percolation, the temperature coefficient of resistivity is negative, and the temperature dependence of the resistivity is close to logarithmic. Annealed at high temperature, the large resistivity with a $-\log(T)$ dependence changes to a small metalliclike resistivity, while the giant Hall effect disappears.² Upon annealing at 520°C , the resistivity decreases more than one order of magnitude, in agreement with the previous measurements.^{2,5}

Similar TEP and resistivity were measured in Fe-SiO_2 films near the percolation where there is a giant Hall effect. Shown in Fig. 3 are (a) TEP and (b) resistivity as functions of temperature for $x=0.56$ and 0.67 , respectively. The dashed line in (b) is a fit to $-\log(T)$ dependence. Again, a similar $-\log(T)$ dependence of resistivity was observed in Fe-SiO_2 films for $x=0.56$ which is slightly above the percolation threshold ($x_c \sim 0.51$). Associated with a weak temperature dependent resistivity, there is a weak temperature dependent TEP. These results suggest that whenever there is a giant Hall effect, the conduction mechanism is such that it gives rise to a rather small and temperature insensitive TEP, independent of the sign of the carrier. The annealing process was failed to perform on the Fe-SiO_2 due to the easy oxidation of iron. However, a small and temperature insensitive TEP characterizes the as-deposited percolating magnetic nanostructures having giant Hall effect, in addition to a large resistivity having a $-\log(T)$ dependence in both systems.

To our knowledge, there are no materials that have such unusually combined transport behavior, namely a large Hall resistivity and a small TEP. A large Hall effect usually indicates a small effective carrier. A loss of carrier in originally a metallic system is often associated with the opening of a gap at the Fermi surface.¹⁵ Associated with an existence of a gap, thermal electric power should behave like a semiconductor, with its value increasing as decreasing temperature. Failure to observe such a behavior indicates that the system

is not like a doped semiconductor and that the disorder plays a crucial role in the electron transport process. It is important to note that the temperature insensitive TEP is a signature of mixed valence conductors¹⁰ including cuprate superconductors,¹⁶ or amorphous and quasicrystalline metals.¹³ In the mixed valence metals, the value of the temperature insensitive TEP is governed by the entropy per carrier according to $S = (k/e) \ln[c/(1-c)]$, if the relevant disorder energy W for the carrier is either much smaller or much larger than kT , where c and $1-c$ are the probability of the two disordered states.

If the disorder can give rise to a temperature insensitive TEP, what types of disorder could give rise to a virtually zero TEP and a zero carrier density at the same time? In order to answer this question, let us first concentrate on one small nanometer-sized particle in the conduction channel.¹⁷ There are two additional energy scales when the metal particle reduces its size. One is the quantized energy level spacing that is inversely proportional to the number of the atoms in the particle. The other is the charging energy, or the energy required to add one more electron into the particle, which is inversely proportional to the capacitance or the size of the particle. From previous transmission electron microscope, Hall, and resistivity studies upon annealing, particles size of order 2–3 nm were identified to be crucial in determining the effective carrier and thus the conduction mechanism.⁵ In terms of the characteristic energy, 2 and 3 nm particles correspond to the level spacing ΔE of 3 meV and 1 meV assuming Fermi energy of 8 eV,¹⁸ or the charging energy E_c of 150 meV and 100 meV assuming a dielectric constant of 4.¹⁷ It is clear that the charging energy E_c is much larger than both the level spacing ΔE and thermal energy kT at room temperature. When there is a large charging energy E_c , such small nanometer-sized particles will generally not carry current. However, at some special size, the small particle can have an equal ground state energy for holding N and $N+1$ electrons, and hence could freely add and subtract one electron without causing energy. Only these special “conducting” particles can then carry current. Such a physical picture on a single nanometer-sized metal particle was firmly established via conductance measurements at low temperature.¹⁷ Moreover, Thermopower studies in such a quantum dot system showed both experimentally¹⁹ and theoretically²⁰ that whenever there is a peak in the conductance, there is a zero thermopower. This suggests that carriers via these special “conducting” nanometer particles do not carry entropy.

In percolating magnetic nanocomposites, there are nanometer-sized particles in the conduction channels. These nanometer-sized particles play the role of quantum dots in controlling the conduction mechanism of the system. Because there is a smooth size distribution, only a fraction of them “conducting,” correspond to a particular particle size having the same energy for N and $N+1$ electrons. As a result, the effective carrier is reduced. This picture explains the loss of the effective carrier when there are nanometer particles in the percolating channels. For these special conducting particles, there is an equal probability ($c \sim 1-c$

~ 0.5) for holding N and $N+1$ electrons, and hence the entropy per carrier is simply $(k/e) \ln[1/(1-c)]$ which is close to 0, similar to the quantum dot system.^{17,18} Upon annealing, these nanometer-sized particles grow. When small particles disappear eventually in the percolation channels, the conductors are all determined by the metallic ones, and the carrier returns to the typical metallic value. As a result, the giant Hall effect disappears, and both the resistivity and the TEP changes to a linear temperature dependence, indicative of the recovery of the normal metallic behavior.

The present physical picture of a large charging energy of nanometer particles in the percolation channels is not limited to the magnetic nanostructure. It could have a general impact in understanding the transport behavior in percolating metal-insulating nanocomposites. Many materials near percolation show a $-\log(T)$ dependence from room temperature.^{19,20} Specifically, we predict that in these nanostructures having $-\log(T)$ dependence, there could be enhanced Hall resistivity and reduced thermal electric power, compared to their corresponding macroscopic composites or homogeneous conducting materials.

Fe_xSe_y films were prepared on GaAs(001) substrates by a selenization of Fe films using molecular beam epitaxy equipment. Structural and magnetic properties of Fe_xSe_y thin films during their selenization process were studied. The selenized films obtained consisted of polycrystalline grains of 100–700 nm. A magnetic anisotropy of in-plane/perpendicular to the films was weakened by increasing the selenization ratio of the samples, which was interesting in contrast to the fact that the grain size of the films became larger. © 1998 American Institute of Physics.

I. INTRODUCTION

Recently, there has been increased research activity in the area of diluted magnetic semiconductors and ferromagnet/semiconductor heterostructures such as $\text{Fe}/\text{ZnSe}/\text{GaAs}$,¹ MnAs/GaAs ,² or MnGa/GaAs .³ Fe_xSe_y is expected as an interlayer of the Fe/ZnSe system or a new magnetic material. Characterizations of bulk crystals of FeSe have been reported with Fe_3Se_4 and Fe_7Se_8 structures.^{4,5} Although $\text{Zn}_x\text{Fe}_y\text{Se}$ and FeSe epilayers grown on GaAs(001) have been reported,⁶ Fe_xSe_y thin films have not been studied much. The lattice structure of bulk Fe_3Se_4 and Fe_7Se_8 is NiAs type with ordered Fe vacancies. The origin of the ferromagnetism in these materials associated with Fe vacancies is similar to the case of Fe_7S_8 pyrrhotite. A saturation magnetization of Fe_7Se_8 is 65 emu/cc at room temperature. Curie temperatures of Fe_3Se_4 and Fe_7Se_8 are 314 and 455 K, respectively. Because of their lattice structures, they have a strong magnetocrystalline anisotropy along the c axis.

In our study, Fe_xSe_y thin films were prepared by a selenization of Fe films using molecular beam epitaxy (MBE) equipment.⁷ As previously reported, the Fe/Se composition ratio x/y of the obtained Fe_xSe_y films measured by an energy dispersive x-ray spectroscopy (EDX) was 2/3 or 1/3.⁸ It was different from those of the reported stable structures of bulk Fe_3Se_4 , Fe_7Se_8 , and FeSe epilayers. In this article, structural and magnetic properties of Fe_xSe_y thin films during their selenization process are reported.

II. EXPERIMENTS

Fe_xSe_y thin films were prepared on GaAs substrates by a selenization technique. Semi-insulating nondoped GaAs (001) substrates were used. Fe thin films deposited by a vacuum evaporation on GaAs substrates were selenized in a MBE chamber. Conventional MBE equipment with solid sources was used. The thickness of the Fe films was 600 nm.

The selenization was performed by supplying a Se beam from a K cell for 30–240 min. The Se beam intensity was varied from 2×10^{-8} to 4×10^{-8} Torr. The beam intensity was monitored by an ion gauge which was positioned outside of the growth area. It was found that Fe_xSe_y compound films were obtained by this technique above a substrate temperature of 380 °C.⁷

Depth profiles of the selenized thin films were measured by using Auger electron spectroscopy (AES). Surface images of the films were observed by a scanning electron spectroscopy (SEM). The magnetization of the films was measured by a vibrating sample magnetometer (VSM) at room temperature.

III. RESULTS AND DISCUSSION

Fe thin films were selenized from their surfaces in the selenization process as shown in inserts in Fig. 1. Figure 1 shows depth profiles of Fe, Se, Ga, and As measured by the AES from the sample selenized with Se beam intensity of 4×10^{-8} Torr for 60 min at a substrate temperature of 380 °C. It is found that a partial region from the surface of the sample is selenized and that the sample consists of a $\text{Fe}_x\text{Se}_y/\text{Fe}/\text{GaAs}$ structure. The intensities of signals of Fe and Se are constant in the selenized region of the sample. It indicates that the layer consists of an Fe_xSe_y compound with a constant composition ratio of Fe/Se. A selenized ratio of $\text{Fe}_x\text{Se}_y/\text{Fe}$ is defined as a ratio of Fe_xSe_y layer thickness against a total film thickness of $\text{Fe}_x\text{Se}_y + \text{Fe}$. The selenized ratio of the sample shown in Fig. 1 is calculated to be 35%.

Samples with various selenized ratios were prepared by varying the selenization time and Se beam intensity at a substrate temperature of 380 °C. In this article, samples with selenized ratios in the range of 6%–74% were investigated.

From the observed SEM surface images of the films, it was found that the films consisted of polycrystalline grains. A dependence of the grain size of the films on the selenized ratio is indicated in Fig. 2. The grain size became larger with the increase of the selenized ratio of the films. The Fe thin

FIG. 1. Depth profiles of Fe, Se, Ga, and As of the selenized thin film measured by Auger electron spectroscopy. The sample was selenized for 60 min with a Se beam intensity of 4×10^{-8} Torr at a substrate temperature of 380 °C. The inserts are schematic diagrams of the selenization process of Fe film on GaAs(001) substrate on molecular beam epitaxy equipment.

films before selenization were polycrystalline with a smooth surface. The grain size was assumed to be of the order of film thickness (600 nm).

Figure 3 shows M - H curves of the selenized films measured by the VSM. An external magnetic field, H was applied along the GaAs [110] axis which was the in-plane direction of the film. Similar M - H curves were obtained from these samples in measurements with the applied magnetic field along [100] and [010] axes. The samples exhibited isotropic magnetic properties in the in-plane direction of the films. The coercive force calculated from the measured in-plane M - H curves of these samples was about 250 Oe, which did not depend on their selenized ratio. A saturation magnetization (M_s) of the samples decreased with the increase in the selenized ratio as shown in Fig. 4. This decrease in the saturated magnetization was attributed to a decrease of Fe atomic concentration in the films. The saturation magne-

FIG. 2. Dependence of grain size obtained from the SEM observations of the selenized films on their selenized ratio.

FIG. 3. In-plane magnetic properties (M - H curve) of the selenized films measured by VSM. The external magnetic field, H was applied along GaAs[110] axis, which was the in-plane direction of the films. The selenized ratios of the samples are 11%(a), 35%(b), and 74%(c), respectively.

tization M_s of the Fe_xSe_y film was 120 emu/cc, which was larger than the reported value of M_s in bulk Fe_7Se_8 (65 emu/cc at 290 K).⁴

Figure 5 shows the M - H curves of the selenized films recorded by applying the magnetic field along the GaAs [001] axis, perpendicular to the films. The magnetic anisotropy between the in-plane and perpendicular directions of the film was weakened with the increase of the selenized ratio of the samples. This is because the thickness of the Fe layer decreases and that the Fe_xSe_y thin films exhibit an isotropic magnetization both in-plane and perpendicular to the film. The grain size of the samples increased with the increase in their selenized ratio, whereas the magnetic anisotropy in-plane/perpendicular to the films was weakened. As the structure of the obtained Fe_xSe_y thin films is different from the reported structures of both bulk and epilayer, it has been difficult to determine a crystal structure of the Fe_xSe_y samples from x-ray diffraction measurements at this moment. A further study on structural analysis by using transmission electron microscopy is required.

FIG. 4. Dependence of saturation magnetization (M_s) on the selenized ratio calculated from the in-plane M - H curves of the selenized films.

FIG. 5. Perpendicular magnetic properties (M - H curve) of the selenized films measured by VSM. The external magnetic field H was applied along the GaAs[001] axis, perpendicular to the films. The selenized ratios of the samples are 11%(a), 35%(b), and 74%(c), respectively.

IV. CONCLUSION

Structural and magnetic properties of the selenized Fe thin films prepared on GaAs(001) substrates were studied. The films consisted of polycrystalline grains 100–700 nm. The size of the grains became larger with the increase in the

selenized ratio defined by the thickness ratio of $\text{Fe}_x\text{Se}_y/(\text{Fe}_x\text{Se}_y + \text{Fe})$. The saturation magnetization of the selenized films decreased with the increase in selenized ratio. It was also found that the magnetic anisotropy of in-plane/perpendicular to the films was weakened with the increase in selenization ratio, which was interesting in contrast to the fact that the grain size of the films became larger.

Magnetic properties of the new phase of SrRuO_3 having a magnetic ordering temperature of 140 K (low- T_c phase) is compared against that of the normal ferromagnetic phase of $T_c = 160$ K (high- T_c phase). The symmetric ac susceptibility curve and an S-shaped M vs H curve of the low- T_c phase suggests a spin-glasslike behavior. However, the value of M at 80 K is comparable for both the phases and the low- T_c phase shows no magnetic aging effect expected for a spin glass. The low- T_c phase is thus a ferromagnetic phase, the difference in the magnetic behavior of the low- T_c phase from that of the high- T_c phase probably originates from the domain structure. © 1998 American Institute of Physics. I. INTRODUCTION

The ferromagnetic perovskite oxide, SrRuO_3 , offers wide technological applications owing to its high electrical conductivity and the fact that thin films of high thermal and chemical stability can be fabricated.¹ Polycrystalline and single crystal samples of SrRuO_3 , usually synthesized at or above 1200 °C, undergo a paramagnetic to ferromagnetic transition below $T_c = 160$ K.² The Curie temperature of SrRuO_3 is known to decrease linearly with an increase in the applied pressure.³ Identical behavior is observed with increasing x in $\text{Sr}_{1-x}\text{Ca}_x\text{RuO}_3$; the T_c decreases with x and CaRuO_3 with $x = 1$ is an antiferromagnetic metal.⁴ Studies on transport and magnetic properties of thin film samples of SrRuO_3 showed that T_c for some of the films is 140 K (Ref. 1) and if the film thickness is increased further, $T_c = 160$ K is obtained (no intermediate T_c value is reported).⁵ We have shown recently that polycrystalline samples also show similar magnetic behavior.⁶ Polycrystalline SrRuO_3 when synthesized below 1150 °C showed a magnetic transition at 140 K (low- T_c phase) and if the processing temperature is increased above 1150 °C, the phase with $T_c = 160$ K (high- T_c phase) is obtained without any drastic modification of crystal structure. The crystal structure of the high- T_c phase of SrRuO_3 is related to the orthorhombic GdFeO_3 structure with lattice parameters $a = 5.57$ Å, $b = 5.53$ Å, and $c = 7.85$ Å.⁷ The low- T_c phase also has the same structure with only a marginal difference in the basal plane lattice parameters, $a \approx b \approx 5.6$ Å.⁶

The observed difference between the shape of the ac susceptibility curves of the low- and high- T_c phases was initially ascribed to a different type of magnetic ordering for the low- T_c phase compared to the ferromagnetic ordering of the high- T_c phase.⁶ In this paper we report the results of a comparison of the magnetic behavior of the two phases of SrRuO_3 .

II. EXPERIMENT

The synthesis of the low- and high- T_c phases of SrRuO_3 was previously reported.⁶ Initial studies showed that a small fraction of the high- T_c phase is always present in the low- T_c phase (as evidenced from a small hump in the ac susceptibility curve at 160 K) which could not be eliminated by varying the synthesis or processing conditions. Formation of the compounds was checked by powder x-ray-diffraction measurements. The microstructural features of both the samples were obtained using a Leica-Cambridge 440 scanning electron microscope (SEM). SEM revealed that the particles were almost spherical with comparable particle sizes, ~ 300 nm and ~ 500 nm for the low- and high- T_c phases, respectively. ac susceptibility was measured using mutual inductance method in an APD close cycle helium cryostat in the temperature range 15–300 K at 27 Hz and 10 Oe. High field dc magnetization and the field cooled (FC) and zero field cooled (ZFC) magnetization studies (80–300 K) at 100 Oe were performed using a PAR EG&G vibrating sample magnetometer, Model 4500. All the experiments on both phases were carried out under identical conditions.

III. RESULTS AND DISCUSSION

Temperature variation of the inverse magnetic susceptibility of the two different phases of SrRuO_3 are shown in Fig. 1. From the magnetization data, T_c is obtained as ~ 160 K and ~ 140 K for the two phases. In the paramagnetic region, above 225 K, both the $\chi^{-1}(T)$ curves follow Curie-Weiss behavior. The calculated effective magnetic moment, μ_{eff} , and the paramagnetic Curie temperature, Θ , for the high- T_c phase are $2.78\mu_B$ and 165 K, and the corresponding values for the low- T_c phase are $2.73\mu_B$ and 144 K, respectively. The μ_{eff} values are close to that expected for an $S = 1$ system (in SrRuO_3 , Ru^{4+} which is a d^4 ion is present in the low spin state $S = 1$). The lower value of T_c for the new phase is due to the larger distortion of the RuO_6 octahedra which in turn changes the Ru-Ru exchange integral

FIG. 1. $\chi^{-1}(T)$ curves of the two different phases of SrRuO_3 showing Curie-Weiss behavior above 225 K, (a) low- T_c phase, $T_c = 140$ K and (b) high- T_c phase, $T_c = 160$ K.

compared to that of the high- T_c phase and not due to the difference in particle size as the particle sizes of both phases are comparable.

Figure 2 shows the ac magnetic susceptibility curves of the two phases of SrRuO_3 . The high- T_c phase shows a sharp peak corresponding to the ferromagnetic transition at 160 K whereas for the low- T_c phase, a symmetric peak is obtained at 140 K apart from the small hump at 160 K which is due to the contribution from the high- T_c phase. The difference between the shape of the two curves indicates that the type of magnetic ordering of the low- T_c phase is probably different from that of the other phase. Symmetric ac susceptibility curves are usually expected for a spin glass⁸ whereas the behavior observed for the high- T_c phase is similar to that reported previously³ for SrRuO_3 and is assigned to the Hopkinson effect,⁹ or to that of cluster-glass-type compounds.¹⁰

Figure 3 shows the M vs H curves of the two phases recorded at 80 K up to a field strength of 15 kOe. Interestingly, the low- T_c phase shows a behavior different from that of the high- T_c phase. The magnetization curve is more or less S shaped and the total magnetization at 15 kOe is slightly less for this phase though the value is very high compared to spin glasses. The symmetric ac susceptibility curve with the S-shaped $M-H$ curve is indicative of a spin-

FIG. 2. χ_{ac} vs T curves of (a) low- T_c phase and (b) high- T_c phase of SrRuO_3 .

FIG. 3. The magnetization curves of (a) low- T_c phase and (b) high- T_c phase of SrRuO_3 .

glasslike behavior⁸ of the low- T_c phase. The reduced remanent magnetization, $R_M = M_r/M_s$, where M_r and M_s are the remanence and saturation magnetization (at 15 kOe), is identical for both the phases (~ 0.77). For polycrystalline ferromagnetic samples, this ratio is a measure of the anisotropy energy and the observed value is in the range expected for such specimens.¹¹ This indicates that the low- T_c phase is another ferromagnetic phase of SrRuO_3 . The above value of R_M is close to that calculated [using $R_M = 0.25n \sin(\pi/n) \approx 0.74$, where n is the number of equivalent directions] for a planar distribution of four easy directions in which two types of uniaxial anisotropies act simultaneously.¹²

In Fig. 4, the FC and ZFC curves of the two phases are compared. For the high- T_c phase, the irreversibility starts at the T_c . Both the low- and high- T_c phases show large and comparable differences between the FC and ZFC magnetization values at 80 K and show identical behavior. Owing to the presence of a small fraction of the high- T_c phase in the low- T_c phase, the FC and ZFC curves start deviating at 160 K for the low- T_c phase as well. This suggests that the low- T_c

FIG. 4. The temperature dependence of FC and ZFC magnetization of SrRuO_3 measured at 100 Oe, (a) low- T_c phase and (b) high- T_c phase.

phase is not related to a spin-glass or cluster-glass system. It may also be noted that the total magnetization of the low- T_c phase is only slightly smaller than that of the high- T_c phase, in contrast to the very small magnetization expected for a true spin-glass system.

We have performed magnetic relaxation experiments on both phases to find whether there is any difference in the behavior between the two systems. For this, the samples were cooled across T_c in a magnetic field of 100 Oe to a temperature, $t=0.7T_c$, and the magnetic field was switched off after a waiting period $t_w=100$ s. The residual magnetization was recorded as a function of time (for 10^5 s) keeping the temperature constant. The experiment was also performed with $t_w=3000$ s. Both the low- and high- T_c phases behaved in a similar manner, with no aging effect. Absence of aging effect for both the phases then indicates that the low- T_c phase is also undergoing a ferromagnetic transition at 140 K. The observed difference in the shape of the ac susceptibility curve as well as the S-shaped $M-H$ curve of the low- T_c phase is then probably a manifestation of the difference in the domain structure or the inequality of the two types of uniaxial anisotropies, which needs to be investigated further.

Growth and characterization of epitaxial thin films of conductive ferromagnetic oxide SrRuO₃

C. B. Eom,^{a)} R. A. Rao, Q. Gan, and D. B. Kacedon

Department of Mechanical Engineering and Materials Science, Duke University, Durham, North Carolina 27708

We have grown epitaxial thin films of the conductive ferromagnetic oxide SrRuO₃ on vicinal (001) SrTiO₃ substrates with different miscut angles and miscut direction. Scanning tunneling microscopy and x-ray diffraction studies indicate that when the miscut angle of the substrate is small ($\alpha \leq 1^\circ$), the films grow by a combination of two-dimensional nucleation and step flow leading to a two domain in-plane texture. As the miscut angle of the substrate is increased, complete step flow growth occurs resulting in single domain thin films if the miscut direction is close to the [010] direction. When the miscut direction of the substrate is changed towards the in-plane [110] direction, two directional step flow growth occurs leading to two domain texture with both domains being present in equal volume fraction. Such differences in the growth mechanism and domain structure of the films lead to significant differences in their magnetization and magnetotransport behavior. © 1998 American Institute of Physics. [S0021-8979(98)31011-7]

Epitaxial thin films and heterostructures of magnetic oxide materials have great potential for novel electronic and magnetic device applications. However, the properties of these devices are sensitive to the surface morphology and microstructure of the thin films. Furthermore, atomic scale control of the surface morphology and interfaces is very important in the fabrication of spin-polarized tunneling¹ in colossal magnetoresistive (CMR) manganites² and other multilayered heterostructure devices. Therefore, controlling the growth mechanisms of magnetic oxide thin films is essential for device applications. Recently, we have controlled the growth of magnetic metallic oxide SrRuO₃ thin films³ in three different growth modes and studied the influence of the growth mechanism on domain structure⁴ by using substrate miscut and lattice mismatch as additional growth parameters. In this report, we elaborate on the influence of miscut angle and direction of vicinal (001) SrTiO₃ substrates on the step flow growth, the resulting domain structure, and the magnetotransport properties of SrRuO₃ thin films.

SrRuO₃ is an itinerant ferromagnet with a Curie temperature of about 160 K in the bulk material. It has a GdFeO₃-type pseudocubic perovskite structure with a bulk lattice parameter of 3.93 Å. This material exhibits strong magnetocrystalline anisotropy in single crystal bulk^{5,6} and single domain thin film⁷ samples. Single crystal epitaxial SrRuO₃ thin films have been grown on miscut (001) SrTiO₃ substrates,⁸ which allows us to study intrinsic anisotropic materials behavior.

The SrRuO₃ thin films were deposited from a 2 in. diameter stoichiometric composite target using a 90° off-axis sputtering technique^{9,10} on vicinal (001) SrTiO₃ substrates. During deposition, the operating pressure was held at 200 mTorr (60%Ar/40%O₂) and the substrate block temperature was in the range of 600–680 °C. After deposition, the samples were cooled down to room temperature in an oxygen pressure of 300 Torr. Films with thickness in the range

of 1000–3000 Å were deposited. At these growth conditions, the SrRuO₃ (110) plane grows readily on the SrTiO₃ (001) face, as the energetically favorable direction for fast growth. All the miller indices for SrRuO₃ referred to in this work are based on the orthorhombic unit cell.

Vicinal (001) SrTiO₃ substrates with miscut angle (α) in the range of 0°–4° and miscut direction varying from and towards the in-plane [010] direction ($\beta \approx 0^\circ$) to close to in-plane [110] direction ($\beta \approx 45^\circ$), were used to investigate the effect of miscut angle and direction. The growth mechanism and surface morphology of the films were studied by STM and atomic force microscopy (AFM). All the films were scanned such that the scan direction (one edge of the image) was parallel to the substrate [010] direction. The crystallographic domain structure was studied by four circle x-ray diffraction. Due to the small lattice mismatch between the film and substrate ($\sim 0.64\%$), all the films had a coherent growth resulting in a strained lattice with in-plane lattice parameters close to that of the substrate (3.91 Å) and an out-of-plane lattice parameter of 3.96 Å. Furthermore, all the films had a purely (110) texture normal to the substrate.

The influence of α was studied by comparing films deposited on substrates with similar β values ($\beta \leq 12^\circ$) but different α . On 0° miscut or exact (001) SrTiO₃ substrates, the film grows by two-dimensional nucleation resulting in a smooth surface and a two domain in-plane texture as described in Ref. 3. As the miscut angle of the substrate is increased, the substrate surface shows a periodic step terrace structure with the terrace width being determined by the miscut angle of the substrate. For vicinal substrates with miscut direction close to the in-plane [010] axis ($\beta \sim 0^\circ$), the (010) plane of SrTiO₃ is also preferentially exposed at the steps on the substrate which leads to a step flow growth mechanism.¹¹ If the miscut angle is too small, then the terrace width on the substrate is larger than the critical surface diffusion length of the film adatoms. As a result, the supersaturation of the adatoms reaches a critical value on the terraces and two-

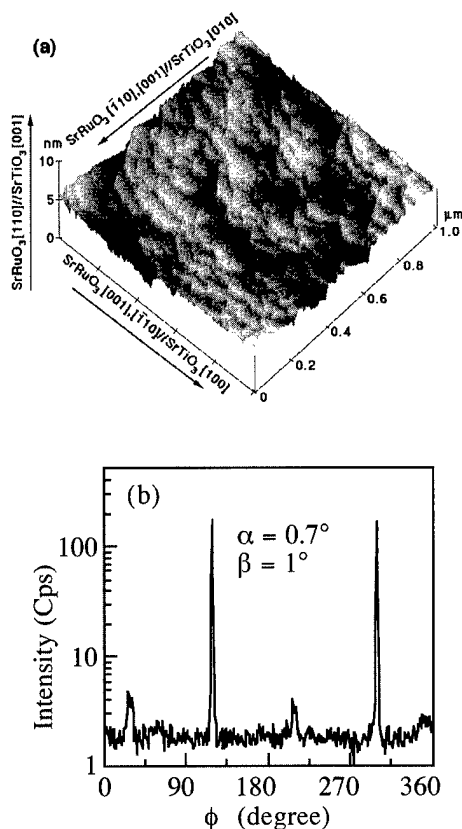

FIG. 1. SrRuO₃ thin film on (001) SrTiO₃ substrate with $\alpha=0.7^\circ$ and $\beta=1^\circ$: (a) STM image showing meandering steps and (b) x-ray ϕ scan of the off-axis (221) reflection.

dimensional nucleation occurs on the terrace. The film growth then proceeds by a combination of step flow and two-dimensional nucleation.

Figure 1(a) shows the STM image of a SrRuO₃ film deposited on vicinal (001) SrTiO₃ substrate with $\alpha=0.7^\circ$ and $\beta=1.0^\circ$. The film surface shows meandering semicircular shaped steps, which indicate that the growth did indeed proceed by a combination of step flow and two-dimensional nucleation, as expected. The step height on the film varies between 4 and 12 Å. This film has a smooth surface with a root mean square (rms) roughness of 5 Å over a $1\ \mu\text{m}\times 1\ \mu\text{m}$ scan area. The x-ray ϕ scans of the (221) reflection of the film is shown in Fig. 1(b). Four peaks are observed indicating a two domain structure with an in-plane alignment of SrRuO₃[$\bar{1}10$], [001]//SrTiO₃[010] and SrRuO₃[001], [$\bar{1}10$]//SrTiO₃[100]. However, due to the partial step flow growth, the [$\bar{1}10$] direction of SrRuO₃ tends to align along the miscut direction or [010] direction of the substrate. Therefore, the domain with an epitaxial arrangement of SrRuO₃[$\bar{1}10$]/SrTiO₃[010] and SrRuO₃[001]/SrTiO₃[100] is found to be predominant.

As the miscut angle of the substrate is increased to greater than 2° the film grows completely by step flow growth and no two-dimensional nucleation is observed. The film surface typically shows straight steps with step bunching, although half and single unit cell high steps can be distinguished in some of the bunched steps. Figure 2(a) shows the STM image and section analysis of a SrRuO₃ film grown on a vicinal (001) SrTiO₃ substrate with $\alpha=4.1^\circ$ and $\beta=11^\circ$. The step height on the film surface varied between 10

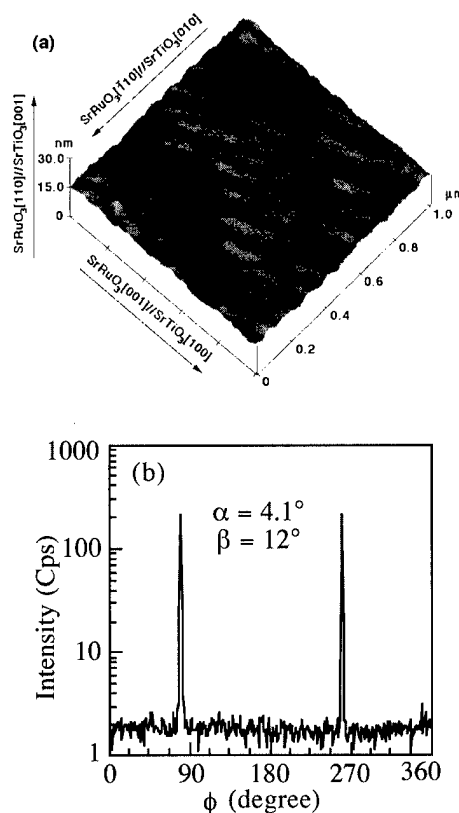

FIG. 2. SrRuO₃ thin film on (001) SrTiO₃ substrate with $\alpha=4.1^\circ$ and $\beta=11^\circ$: (a) STM image showing straight steps and (b) x-ray ϕ scan of the off-axis (221) reflection.

and 37 Å. The rms surface roughness was found to be 9.2 Å over a $1\ \mu\text{m}\times 1\ \mu\text{m}$ scan area. The complete one directional step flow growth led to a single domain texture as evidenced by two peaks separated by 180° in the x-ray ϕ scans of the (221) reflection shown in Fig. 2(b). The in-plane epitaxial arrangement is SrRuO₃[$\bar{1}10$]/SrTiO₃[010] and SrRuO₃[001]/SrTiO₃[100]. As the miscut angle is further increased, the step height on the film surface increases leading to a corresponding increase in the rms surface roughness of the films. The increase in the step height with the miscut angle is consistent with the bunching phenomenon observed in the step flow growth model.

We have also investigated the effect of changing the miscut direction, β , on the growth mechanism and domain structure, by comparing films deposited on 2° miscut SrTiO₃ substrates with $\beta=12^\circ$ and $\beta=45^\circ$. The SrRuO₃ film deposited on the former substrate showed a straight step pattern. The film surface shows step bunching with the bunched step height varying between 10 and 30 Å. The rms surface roughness is 8 Å over a $1\ \mu\text{m}\times 1\ \mu\text{m}$ scan area. Although the miscut direction is 12° away from the in-plane [010] direction, the film surface shows only a few kink sites, indicating that the step flow is dominated by the majority planes exposed at the step sites. This one directional step flow leads to a single domain texture with the same in-plane epitaxial alignment as the film on 4.1° the miscut substrate, as shown in Fig. 2(b).

However, on the latter substrate ($\beta\sim 45^\circ$) both the (010) and (100) plane are exposed in equal proportions at the step sites. Therefore, it is expected that step flow growth occurs-

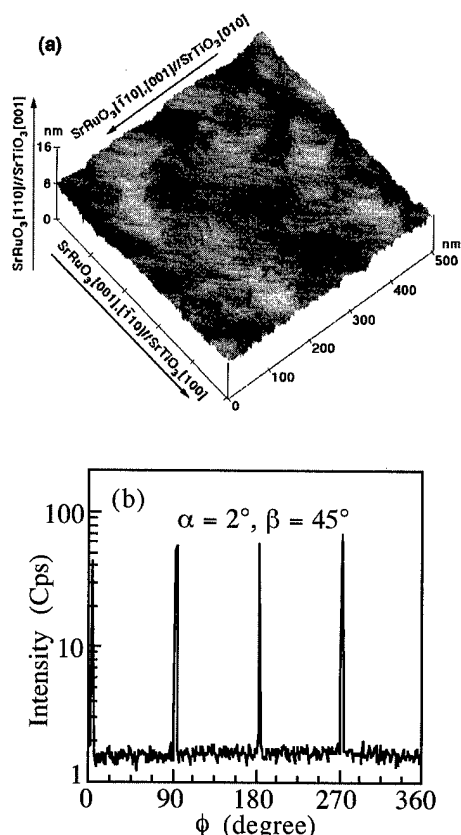

FIG. 3. SrRuO₃ thin film on (001) SrTiO₃ substrate with $\alpha=2.0^\circ$ and $\beta=45^\circ$: (a) STM image showing two directional step flow and (b) x-ray ϕ scan of the off-axis (221) reflection.

equally along both directions with no single direction dominating the growth. This should lead to a two domain in-plane texture.

Figure 3(a) shows the STM image of a SrRuO₃ film deposited on the substrate with $\beta=45^\circ$. As expected, the film surface shows a step pattern indicating step flow growth in two orthogonal directions. The bunched step height on the film surface varies between 8 and 25 Å. Single and half unit cell high steps can be distinguished in the bunched steps. Due to the two directional step flow, several kink sites are observed on the film surface. The film surface has a rms surface roughness of 6.4 Å over a $1\mu\text{m}\times 1\mu\text{m}$ scan area. Figure 3(b) shows the x-ray diffraction ϕ scans of the (221) reflection for this film. Four peaks separated by 90° from each other are observed, indicating a two domain in-plane alignment. Furthermore, the four peaks are of equal intensity which implies that the two domains are present in equal volume fraction.

Such changes in the growth mechanism and domain structure can lead to significant differences in the magnetization and magnetotransport properties of the film.

Figure 4 shows the magnetoresistance (MR) as a function of field for the single domain film obtained on miscut substrate with $\alpha=2^\circ$, $\beta=12^\circ$ and the two domain film obtained on miscut substrate with $\alpha=0.7^\circ$, $\beta=1^\circ$, respectively. The magnetoresistance is calculated as: $\text{MR} = [\rho(H) - \rho(0)] / \rho(0)$, where $\rho(H)$ and $\rho(0)$ are the resistivity at a field H and at zero field, respectively. As is evident from Figs. 4(a) and 4(b), the single domain film shows anisotropic behavior when the field is applied along the two

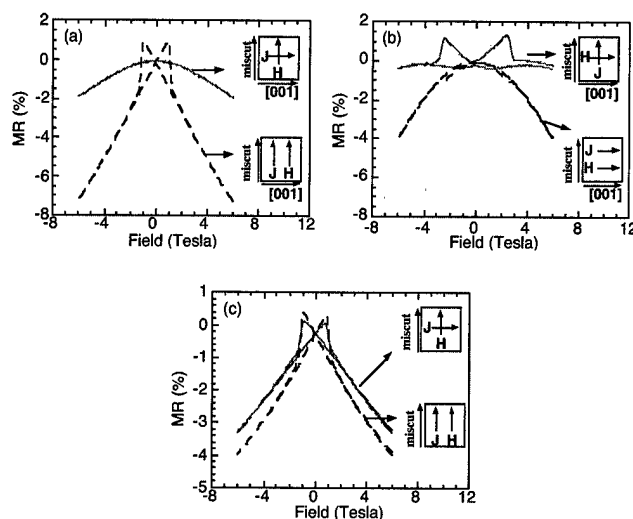

FIG. 4. The magnetoresistance (MR) as a function of applied field at 5 K for (a) and (b) single domain film on (001) SrTiO₃ substrate with $\alpha=2^\circ$ and $\beta=12^\circ$ along the two different directions of applied field and (c) two domain film on (001) SrTiO₃ substrate with $\alpha=0.7^\circ$ and $\beta=1^\circ$. The inset shows the field (H) and current (J) directions with respect to the miscut direction of the substrate.

different in-plane directions. This anisotropic behavior is attributed to the inherent magnetocrystalline anisotropy of SrRuO₃ which is a result of the large spin-orbit coupling of Ru. Figure 4(c) shows the MR versus field behavior for the two domain film with field applied along the miscut direction. An almost identical MR behavior is expected when the field is also applied perpendicular to the miscut direction as observed in multidomain films deposited on (001) LaAlO₃ substrates.¹² Thus, the anisotropy in the magnetic and magnetoresistance properties of SrRuO₃ thin films are dependent on the crystallographic domain structures of the films.

The low temperature magnetic properties of the Li_2CuO_2 compound have been investigated by means of superconducting quantum interference device magnetometry. We find in addition to an antiferromagnetic phase below 9.5 K a ferromagnetic-like steep rise of the magnetization around 2.8 K. The observed low temperature behavior is discussed by considering second and fourth order magnetocrystalline effective anisotropy coefficients, in addition to the exchange couplings reported in the literature. © 1998 American Institute of Physics. [S0021-8979(98)31111-1]

The magnetic properties of ternary copper oxides are currently of considerable interest, in particular with respect to high T_c superconducting compounds. Unlike these perovskite systems the Li_2CuO_2 compound investigated here exhibits an orthorhombic structure consisting of CuO_2 planes stacked along the crystallographic c axis, and separated by Li-rich layers. Within a CuO_2 plane the Cu ions are lined up in chains.^{1,2} Thus this compound was expected to exhibit magnetic properties reminiscent to a one dimensional magnet.³ The magnetic structure of this compound as determined by neutron diffraction² may be described as follows: the magnetic moments within the CuO_2 planes are ferromagnetically ordered, whereas neighboring planes are coupled antiferromagnetically (AF) along the c axis. In addition to an AF ordering transition at $T_N = 9.5$ K, we observe at temperatures below 2.8 K the appearance of a ferromagnetic component along the direction of the applied magnetic field. We argue that the observed magnetic behavior corresponds to a noncollinear arrangement of the spin layers due to competing magnetocrystalline anisotropies and interlayer exchange coupling. Experimental evidence supporting this argument is presented.

The procedure for fabricating the polycrystalline Li_2CuO_2 compound has been described elsewhere.² The x-ray diffraction patterns of the sample corresponds to a *single crystallographic phase*. The magnetic properties have been measured by means of superconducting quantum interference device (SQUID) magnetometry with applied magnetic fields up to 10 kOe, and in the temperature range between 2 and 300 K. In all our experiments the temperature dependence of the magnetization is measured during warming

scans. It is important to point out that independent samples fabricated and measured at two different places yield identical structural and magnetic properties.

As has already been reported in the literature,^{1,2} the magnetic properties of the Li_2CuO_2 compound (i) exhibits an AF ground state with a Néel temperature $T_N \approx 9$ K, and (ii) shows a Curie-Weiss behavior of the paramagnetic susceptibility above T_N , with a paramagnetic Curie temperature of about $\Theta \approx -40$ K. In addition we have observed the appearance of a *ferromagnetic* component of the magnetization oriented along the applied magnetic field for temperatures below 2.8 K, cf. Fig. 1. The samples were field cooled (FC) in an applied field of 10 Oe, as well as zero field cooled (ZFC) down to 2.0 K. With increasing temperatures the magnetization for both ZFC and FC conditions were measured by applying a magnetic field of 10 Oe. We notice that both curves overlap above 2.8 K, and show the characteristic kink at the Néel temperature T_N . Note also the change of scale of the magnetization for the data taken above 4 K, cf. Fig. 1(b). In

FIG. 1. Temperature dependence of the magnetization of a Li_2CuO_2 sample (67.3 mg). ZFC denotes cooling the sample down to 2.0 K in zero applied field; FC is cooled in a magnetic field of about 10 Oe. (a) Transition from a noncollinear arrangement of the spin layers to a purely AF phase above 2.8 K. (b) Transition from the AF to the paramagnetic phase, with the Néel temperature $T_N \approx 9.5$ K.

FIG. 2. Magnetic loops of a Li_2CuO_2 sample (67.3 mg) as a function of applied magnetic field. The samples are cooled in zero applied field (ZFC) down to 2.2 K. (a) $T=2.2$ K; first the virgin curve is measured, then the sample is cycled between $H=\pm 10$ kOe. (b) Linear magnetic loops measured at $T=5$ K (\bullet), $T=9$ K (Δ), and $T=14$ K (\blacktriangledown). The hysteresis loop obtained for $T=2.2$ K (\circ) is also shown for comparison.

addition we have monitored the magnetic hysteresis loops $M(H)$ below and above 2.8 K. In the former case we observe a small *remanent magnetization*, cf. Fig. 2(a) for $T=2.2$ K, and a resulting coercive field of about $H_c \approx 12$ Oe. Within these measurements the samples were cooled in ZFC down to 2.2 K. First the virgin magnetization curve $M(H)$ is monitored, then the complete hysteresis loop is measured by cycling the external field through ± 10 kOe. We find that the loops close and the reversible part of the magnetization $M(H)$ is reached for magnetic fields above $|H|=100$ Oe.

No remanence was observed for temperatures above 2.8 K, as shown in Fig. 2(b) for temperatures of about 5, 9, and 14 K. However, for all temperatures investigated the magnetization curves $M(H)$ stay in the linear regime and do not saturate at even the strongest available applied fields, resulting in a high field susceptibility $\chi_{\text{hf}} \approx 2.6 \times 10^{-5}$ emu/gOe at $T=2.2$ K. We note that a complete saturation of the Cu^{2+} ions would render a specific magnetization of about $\sigma_s = 51$ emu/g, assuming $J=1/2$ spins.

In addition we have measured the susceptibility in the paramagnetic phase. A Curie-Weiss behavior was observed, yielding a Curie constant $C_M \approx 0.41$ emu K/mol Oe and the paramagnetic Curie temperature $\Theta \approx -15$ K, which differs from the one reported previously.² From our data we conclude a magnetic moment $\mu \approx 1.05 \mu_B$ per Cu ion, which is consistent with a recent neutron diffraction study yielding a magnetic moment of $\mu \approx 0.96(4) \mu_B$.²

The above results can be explained in terms of a uniaxial magnetocrystalline anisotropy determining the direction of the magnetization with respect to the c axis. Commonly, the uniaxial anisotropy is given as a series in powers of $\cos \theta$, θ being the angle between the magnetization and the c axis. The anisotropic part of the free energy per spin pair may be written as

$$F(T, \theta_1, \theta_2) = -J_c(T) \cos(\theta_1 - \theta_2) - K_2(T) (\cos^2 \theta_1 + \cos^2 \theta_2) - K_4(T) (\cos^4 \theta_1 + \cos^4 \theta_2).$$

$K_2(T)$ and $K_4(T)$ are the second and fourth order *effective*, i.e., temperature dependent, lattice anisotropy coefficients. Expressions of these coefficients as calculated by, e.g., a thermodynamic perturbational expansion of the free energy

FIG. 3. Sketch of the spin arrangements of two neighboring CuO_2 layers for (a) the purely AF phase, and (b) the noncollinear phase. Note that the latter is metastable since it refers to a local minimum of the free energy. It exhibits a finite remanent magnetization, and may vanish above some temperature T_x . θ is the canting angle between the magnetization and the crystallographic c axis.

are given in Ref. 4. Note that for $K_{2,4} > 0$ a magnetization parallel to the c axis is favored ($\theta=0$), and a perpendicular orientation ($\theta=\pi/2$) for $K_{2,4} < 0$. $J_c(T) < 0$ is the *effective* interlayer exchange coupling connecting q nearest neighbors in adjacent CuO_2 layers, and favoring an AF alignment. Minimization of $F(T, \theta_1, \theta_2)$ with respect to θ_1 and θ_2 reveals the equilibrium canting angles. The most stable state is always the purely AF spin arrangement with $\theta_2 = \theta_1 + \pi$ and a vanishing total magnetization. The case of competing anisotropies $K_2 > 0$ and $K_4 < 0$ may result in a canted magnetization,⁴ i.e., $0 < \theta < \pi/2$, cf. Fig. 3(a).

Most importantly, two additional metastable states may occur corresponding to a noncollinear spin arrangement, cf. Fig. 3(b), which may be in parts thermally populated. The respective canting angles θ_1 and $\theta_2 = -\theta_1$ are determined by $J_c(T)$, $K_2(T)$, and $K_4(T)$ (and also by an applied magnetic field if present), and should be close to $\pi/2$. Quite interestingly, due to the *effective* temperature variation of the involved interactions, the metastable state may *vanish* above some temperature T_x , probably around 2.8 K in the present case. However, below T_x and in the absence of an applied field the two metastable states refer to oppositely oriented magnetizations. Since these two states have the same free energy, they are equally populated, but less populated than the purely AF state. The occupation ratio may be given by $\propto \exp(-\Delta F/k_B T)$, where ΔF is the free energy difference between the stable and the two metastable states. An applied magnetic field may cause a different thermal population of these two metastable states, yielding a small but finite remanent magnetization, cf. the hysteresis loop shown in Fig. 2(a). Also shown in this figure is the virgin curve, i.e., the sample was cooled down to 2.2 K in vanishing magnetic field, resulting in equally populated metastable minima and thus in a vanishing remanence. Furthermore, the ZFC magnetization should vanish at temperatures close to $T=0$, since then the equilibrium thermal population of the metastable states would be vanishingly small. A complete description of the model and the theoretical results will be presented elsewhere.

We do not think that T_x refers to a blocking temperature as present in superparamagnetic systems, since our systems exhibit infinitely extended and strongly coupled ferromagnetic layers. Of course each layer may break up into magnetic domains which will determine essentially the behavior of the hysteresis loops, cf. Fig. 2(a).

In conclusion, the low temperature magnetic properties

of the Li_2CuO_2 compound have been investigated by experimental and theoretical means. At temperatures below 2.8 K the pure AF arrangement of the spin layers is disturbed by the appearance of metastable minima of the free energy, referring to a noncollinear spin arrangement. The origin of such spin configuration is the competition between the AF interlayer exchange coupling, and the magnetocrystalline anisotropy causing a canted magnetization. The thermal population of such minima is observed by the appearance of a finite remanence and coercivity below 2.8 K. Above this temperature the metastable states vanish due to the effective temperature dependence of the involved interactions. At elevated temperatures the compound is an antiferromagnet with Néel temperature $T_N \approx 9.5$ K. The high temperature paramagnetic susceptibility, which closely obeys the Curie-Weiss law, reveals a magnetic moment of about $1 \mu_B$ per Cu ion.

After establishing the usefulness of ion implantation to synthesize diluted magnetic semiconductors (DMSs) for the case of $\text{Zn}_{1-x}\text{Co}_x\text{Te}$, we apply this technique to obtain Ni-based DMS which has not been reported before. Ni ions are implanted into a ZnTe film with acceleration energies from 30 to 390 keV to achieve a Ni density of $3 \times 10^{20}/\text{cm}^3$. Magnetic circular dichroism (MCD) spectra show that the Ni ions substitute Zn ions and induce sizable Zeeman splittings of the optical transitions. Analyses of the MCD spectra show that the p - d exchange in $\text{Zn}_{1-x}\text{Ni}_x\text{Te}$ is antiferromagnetic. © 1998 American Institute of Physics. [S0021-8979(98)43811-8]

I. INTRODUCTION

Diluted magnetic semiconductors (DMSs)¹ are solid solutions of II-VI semiconductors with some cations replaced by 3d transition-metal ions. DMS shows a variety of interesting phenomena such as the giant Faraday effect. These anomalous spin-dependent properties of DMS arise from a strong hybridization between the sp band carriers of the host semiconductors and the localized d orbitals of the transition-metal ions in the tetrahedral (T_d) symmetry. Therefore, the properties of DMS should sensitively depend on the transition-metal ions. The sp - d exchange interactions in DMS with different transition-metal ions ranging from Sc to Cu have been investigated theoretically.²⁻⁴ However, only Mn-, Fe-, and Co-based DMS have been studied experimentally. Recently Cr-based new DMS was also synthesized.⁵ But there have been no experimental reports on DMS with Sc, Ti, V, Ni, or Cu ions. These ions do not substitute the cations of the host II-VI semiconductor under the thermoequilibrium conditions in which the bulk crystals were grown. One must develop nonthermoequilibrium synthesis methods to break the solubility limit of the transition metal ions into the host semiconductor materials. We already know such examples. Zinc-blende type $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$ with a Mn concentration higher than $x=0.7$ cannot be obtained as bulk crystals. But epitaxial films of these metastable DMSs have been obtained by the molecular beam epitaxy (MBE).^{6,7} The MBE method was also used to expand the Cr concentration limit in Cr-based DMS⁸ up to at least $x=0.08$. But the MBE method has not successfully synthesized Ni-based DMS.

In this article, we report on the first successful synthesis of Ni-based DMS by using ion implantation method.⁹ We demonstrate that DMS can be synthesized by ion implantation by showing the case of Co-based DMS which has been well-studied. Next we show the synthesis of $\text{Zn}_{1-x}\text{Ni}_x\text{Te}$ and discuss its sp - d exchange interactions.

II. EXPERIMENT

ZnTe films were epitaxially grown on sapphire (0001) substrates by MBE. The typical thickness of the film was about 200 nm. ZnTe films were implanted with ions of energy 30–390 keV to doses up to $1 \times 10^{16}/\text{cm}^2$ at room temperature. The implanted depths estimated for the energy of 200 keV were about 100 nm. Therefore, for the dose of $1 \times 10^{16}/\text{cm}^2$, the concentration of the transition metal ions can be a few percent of the total cations.

Magnetic circular dichroism (MCD) measurements¹⁰ were used to detect the synthesized DMS. MCD measures the relative difference of the circular polarization dependent optical absorption under the applied magnetic field, i.e., $2(K_- - K_+)/ (K_+ + K_-)$, where K_- and K_+ are optical absorption coefficient for σ_- and σ_+ polarizations, respectively. The optical absorption depends on the circular polarization due to the Zeeman splittings of the band structures. Because the strong sp - d exchange interaction of DMS should lead to sizable Zeeman splittings of the optical transitions, the MCD spectroscopy sensitively detects the DMSs and explores their electronic structures. We measured the MCD spectra with alternating σ_+ and σ_- circularly polarized light (50 kHz) produced by a quartz stress-modulator. One degree of MCD corresponds to a 7% difference of optical absorption. The magnetic field was applied along the light propagation direction (i.e., Faraday configuration).

III. SYNTHESIS OF $\text{Zn}_{1-x}\text{Co}_x\text{Te}$ BY ION IMPLANTATION

Figure 1 shows the MCD spectra of ZnTe films with and without the ion implantations. The ZnTe film showed a small positive peak at its band-gap energy E_0 of 2.40 eV [Fig. 1(a)]. This is due to the diamagnetic Zeeman effect of the exciton at the Γ point. This peak became weaker and broader by the defects induced by Zn implantation of the dose of $5 \times 10^{16}/\text{cm}^2$ at 200 keV [Fig. 1(b)]. This shows that the defects do not induce the magneto-optic effect. Therefore we can attribute the appearance of new MCD structures in the

^{a)}Electronic mail: ando@etl.go.jp

FIG. 1. MCD spectra at 5 K and 1 T of (a) pure ZnTe, (b) as-implanted ZnTe:Zn(5×10^{16} Zn/cm²), (c) as-implanted ZnTe:Co(1×10^{16} Co/cm²), and (d) ZnTe:Co(1×10^{16} Co/cm²) after annealing at 500 °C for 1 min. A part of (d) is magnified for clarity.

transition-metal ion implanted films to the change of the electronic states caused by the transition-metal ions. Figure 1(c) is a spectrum of the Co implanted ZnTe film of the dose of 1×10^{16} /cm² at 200 keV. Sharp MCD peaks appeared in a spectral range of 1.4–1.5 eV. Near the band-gap energy E_0 of ZnTe, a broad negative peak appeared. At the photon energy range between 3.5 and 4.5 eV, a complex structure also appeared. A thermal annealing of the Co implanted film at 500 °C for 1 min in a forming gas (90% N₂, 10% H₂) sharpened the spectral structures especially at an energy range higher than 2 eV. It becomes clear that the complex structure near 4 eV is composed of the two dispersion-type structures centered at 3.76 and 4.32 eV. These photon energies are exactly coincident with the energies of the spin-orbit split E_1 and $E_1 + \Delta_1$ optical transitions of ZnTe.

The $d-d^*$ intraionic transitions of the Co²⁺ ion in the T_d symmetry have been experimentally studied in Cd_{1-x}Co_xTe,¹¹ Zn_{1-x}Co_xS,¹² and Zn_{1-x}Co_xSe crystals.¹² Two strong optical transitions from the ground state $^4A_2(^4F)$ to the excited state $^4T_1(^4P)$ were reported at 1.348 and 1.362 eV in Cd_{1-x}Co_xTe. These energies correspond to the two positive MCD peaks at 1.370 and 1.384 eV as shown in the magnified part of Fig. 1(d). The $d-d^*$ transitions are also known to accompany weaker absorption lines at about 0.1–0.2 eV higher energies.¹² The small negative MCD peaks at 1.468 and 1.538 eV of Fig. 1(d) correspond to the weaker absorption lines of the $^4A_2(^4F) \rightarrow ^4T_1(^4P)$ transitions. Therefore the MCD peaks at 1.4–1.5 eV are the fingerprints of Co²⁺ in the T_d symmetry. This is clear evidence that the implanted Co ions substituted Zn ions, at least partly, and that Zn_{1-x}Co_xTe was successfully synthesized.

Appearances of the strong MCD structures at the energies corresponding E_0 , E_1 , and $E_1 + \Delta_1$ critical points are due to a well known strong $sp-d$ exchange interaction in Co-based DMS.¹ At present it is not clear what percentage of the implanted Co ions substituted Zn ions. Only the transition-metal ions in the T_d symmetry sites can induce the

FIG. 2. MCD spectra at 5 K and 1 T of a Ni implanted ZnTe film with Ni density of 3×10^{20} /cc after annealing at 300 °C for 1 min.

$sp-d$ exchange interaction.¹³ The MCD selectively detects the synthesized part of Zn_{1-x}Co_xTe.

IV. Zn_{1-x}Ni_xTe AND ITS $sp-d$ EXCHANGE INTERACTION

We applied the ion implantation method to obtain a heretofore unknown new DMS, Zn_{1-x}Ni_xTe. Ni ions were implanted with five different acceleration energies ranging from 30 to 390 keV to obtain a 200 nm thick implanted layer with a uniform Ni ion density of 3×10^{20} /cm³. The ZnTe:Ni sample annealed at 300 °C for 1 min shows the characteristic MCD structures (Fig. 2) of DMS to be the same as Zn_{1-x}Co_xTe [Fig. 1(d)]. This indicated that Zn_{1-x}Ni_xTe was successfully synthesized.

The polarities of the MCD peaks strongly correlate with the polarity of the $p-d$ exchange interaction. In DMS the $p-d$ exchange interaction is much stronger than the $s-d$ exchange.¹ Then the $p-d$ exchange interaction determines the polarity of the Zeeman split, which in turn determines the polarity of MCD. We have shown that at the E_0 band edge the antiferromagnetic (AF) $p-d$ exchange induces the negative MCD peak, and the ferromagnetic (F) $p-d$ exchange induces the positive MCD peak.⁸ Then the negative MCD peaks at E_0 in ZnTe:Co and ZnTe:Ni films strongly suggest the AF $p-d$ exchange in Zn_{1-x}Co_xTe and Zn_{1-x}Ni_xTe. Indeed, it is well known that the $p-d$ exchange in Co-based DMS is antiferromagnetic.¹

This conclusion of AF $p-d$ exchange interaction in Zn_{1-x}Ni_xTe was also supported from the MCD structures at the E_1 and $E_1 + \Delta_1$ optical transitions (Fig. 3). The spectra of ZnTe, ZnTe:Co, and ZnTe:Ni samples are shown together with that of a MBE grown Zn_{0.95}Cr_{0.05}Te film.⁸ Two peak structures of the pure ZnTe film are both positive at E_1 and $E_1 + \Delta_1$. The ZnTe:Co film clearly shows the inverted polarity of the E_1 MCD peak. The polarity of the $E_1 + \Delta_1$ MCD peak remained the same as that of ZnTe. It has been shown that the hybridization between the d orbitals and the p valence band causes the Zeeman splittings of the E_1 and $E_1 + \Delta_1$ transitions in opposite directions.¹⁴ The E_1 inverted and $E_1 + \Delta_1$ noninverted MCD structures correspond to the AF $p-d$ exchange. If the $p-d$ exchange is ferromagnetic,

FIG. 3. MCD spectra at E_1 and $E_1 + \Delta_1$ of MBE grown ZnTe, MBE grown $\text{Zn}_{0.95}\text{Cr}_{0.05}\text{Te}$ samples, as-implanted $\text{ZnTe:Co}(1 \times 10^{16} \text{ Co/cm}^2)$ and as-implanted $\text{ZnTe:Ni}(1 \times 10^{16} \text{ Ni/cm}^2)$ samples measured at 5 K and 1 T.

we expect the reversed polarities, i.e., noninverted E_1 edge and inverted $E_1 + \Delta_1$ edge. Indeed $\text{Zn}_{0.95}\text{Cr}_{0.05}\text{Te}$, which has a ferromagnetic p - d exchange, showed the expected MCD structures. Judging from these correspondences, the MCD structures at the E_1 and $E_1 + \Delta_1$ edges also indicate the AF p - d exchange in $\text{Zn}_{1-x}\text{Ni}_x\text{Te}$.

The AF p - d exchange in $\text{Zn}_{1-x}\text{Ni}_x\text{Te}$ is reasonable.²⁻⁴ The Γ_8 Luttinger states of the valence band only couple with the three one-electron d states belonging to the t_{2g} representation of the point group T_d . The Ni^{2+} ion has eight d electrons which occupy four e_g and four t_{2g} one-electron orbitals. The spin-up t_{2g} electron states are all occupied. There is only one available vacant spin-down t_{2g} electron state for the electron jump from the valence band. The absence of the spin-up electron jump into the t_{2g} state may be a common reason for the AF p - d exchange in Mn-, Fe-, Co-, and Ni-based DMS. For Ni-based DMS, a huge AF p - d exchange was theoretically predicted.⁴ Quantitative evaluation of the p - d exchange interaction requires information on the mag-

nitude of the Zeeman splitting and numbers of Ni ions which substitute Zn ions. This evaluation is now in progress.

V. CONCLUSIONS

We have shown that the ion implantation technique is a powerful method to synthesize diluted magnetic semiconductors. By using this method Ni-based DMS $\text{Zn}_{1-x}\text{Ni}_x\text{Te}$ has been successfully synthesized for the first time. From the magnetic circular dichroism spectra, the p - d exchange interaction in $\text{Zn}_{1-x}\text{Ni}_x\text{Te}$ is shown to be antiferromagnetic.

Magnetic circular dichroism (MCD) of a ferromagnetic diluted magnetic semiconductor $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ films was measured to clarify their electronic structure. Strong enhancement of MCD by Mn substitution indicated a strong $sp-d$ hybridization. The $p-d$ exchange interaction was concluded to be antiferromagnetic, which was in contrast with the reported ferromagnetic $p-d$ exchange in very diluted paramagnetic GaAs:Mn bulk crystals. The change of the character of the $p-d$ exchange interaction is due to the unique feature of $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ that the relative abundance of the neutral and ionized Mn acceptors controls the $p-d$ exchange. © 1998 American Institute of Physics. I. INTRODUCTION

$\text{Ga}_{1-x}\text{Mn}_x\text{As}$ is a new III-V based diluted magnetic semiconductor (DMS).¹⁻⁴ Single-phase zinc-blende type epitaxial films can be obtained with manganese concentration x up to 0.08. Ferromagnetic ordering was observed by magnetic and magnetotransport measurements. However, little is known of their electronic structure, especially how the Mn d electrons interact with the sp -band electrons in this Mn containing DMS. In this article, we show magnetic circular dichroism (MCD) spectra of $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ epitaxial films, and discuss their electronic structure.

II. EXPERIMENT

$\text{Ga}_{1-x}\text{Mn}_x\text{As}$ thin films were grown on (001) GaAs substrates by the molecular beam epitaxy method at 200–300 °C under As rich conditions.^{2,4} Reflection high energy electron diffraction and x-ray diffraction showed that they are single phase zinc-blende type epitaxial films. No MnAs precipitation was detected by x-ray diffraction. Two $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ samples of $x = 0.005$ (thickness 1.0 μm) and 0.074 (thickness 1.4 μm) were used for this study. Their hole concentrations at room temperature are 1.93×10^{19} and $2.58 \times 10^{20} \text{ cm}^{-3}$, respectively. Ferromagnetic ordering was observed below ≈ 10 K for $x = 0.005$ and below ≈ 60 K for $x = 0.074$.

MCD measures the difference between the reflectance for left and right polarizations.⁵ Alternating polarized light (50 kHz) was produced by a quartz stress-modulator. The direction of input and reflected lights deviate from the film

normal by 10° . One degree of MCD corresponds to 7% difference of reflectivity.

III. RESULTS AND DISCUSSIONS

Figure 1(a) shows the MCD spectrum of GaAs substrate. The structures appear at the energies of the critical points (CPs) of the zinc-blende type band structure, E_0 , $E_0 + \Delta_0$, E_1 and $E_1 + \Delta_1$. The signal between 1.51 and 1.60 eV is the oscillation by the Landau quantization effect. With incorporating manganese ions, the MCD signals near CP are significantly enhanced as shown in Figs. 1(b) and 1(c). This clearly

FIG. 1. Magnetic circular dichroism (MCD) spectra of (a) nondoped semi-insulating GaAs substrate and (b),(c) the epitaxial $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ films at $T = 5$ K and $H = 1$ T. The spectrum of GaAs is magnified ten times because the signal is weaker than that of $\text{Ga}_{1-x}\text{Mn}_x\text{As}$.

FIG. 2. Magnetic field dependence of E_1 MCD at 2.83 eV of $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ ($x=0.074$) at $T=5$ K.

shows that $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ has a typical band structure of the zinc-blende type semiconductors and the strong $sp-d$ mixing occurs at each CP.

The magnetic field dependence of the MCD intensity of the $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ ($x=0.074$) sample at 2.83 eV shows the apparent ferromagnetic behavior (Fig. 2). The MCD signal originates from the E_1 CP of $\text{Ga}_{1-x}\text{Mn}_x\text{As}$, and the MCD spectrum of MnAs (Ref. 6) has no common feature with that of $\text{Ga}_{1-x}\text{Mn}_x\text{As}$. Therefore, we can exclude the possibility that the observed ferromagnetism comes from possible small clusters of MnAs precipitations. The observed ferromagnetism comes from the $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ ternary alloy semiconductor.

The MCD near E_0 CP for the $x=0.005$ sample is shown in Fig. 3. This oscillating structure arises from the optical interference effect within the film. The oscillating period (≈ 160 meV) agrees with the expected period calculated from the film thickness and the refractive index of GaAs. We noted that near the band-gap energy E_0 of GaAs, 1.52 eV, a sharp negative MCD peak is superimposed on the interference pattern. This indicates that the MCD is negative at E_0 in $\text{Ga}_{1-x}\text{Mn}_x\text{As}$. From the negative polarity of MCD at E_0 , we can estimate the character of the $p-d$ exchange. The polarity of MCD is a good indicator of the polarity of the $p-d$ ex-

FIG. 3. MCD spectrum of $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ ($x=0.005$) film near the E_0 critical point. The E_0 point energy of GaAs is shown for comparison by an arrow.

change constant $N_0\beta$. For example, at E_0 CP, the antiferromagnetic (AF) $p-d$ exchange ($N_0\beta < 0$) in $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$ showed a negative MCD peak, and the ferromagnetic (F) $p-d$ exchange ($N_0\beta > 0$) in $\text{Zn}_{1-x}\text{Cr}_x\text{Se}$ showed a positive MCD peak.⁷ This is due to a relation⁵ of MCD with $N_0\beta$ and the $s-d$ exchange constant $N_0\alpha$,

$$\text{MCD} = -(1/4)(N_0\alpha - N_0\beta) \times \langle Sz \rangle (1/R) dR/dE, \quad (1)$$

where $\langle Sz \rangle$ is the average spin per Mn ion, and E is the photon energy. Mn ions in DMS occupy the tetrahedrally (T_d) coordinated sites, and their d orbits mix with the p valence band, not with the s conduction band.⁸ Then the absolute value of $N_0\beta$ should be larger than that of $N_0\alpha$, and the polarity of MCD is determined by the polarity $N_0\beta$. The negative MCD at E_0 CP of $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ corresponds to the AF $p-d$ exchange, $N_0\beta < 0$.

The MCD structures at the E_1 CP and $E_1 + \Delta_1$ CP are also strongly enhanced by the Mn substitution (Fig. 1), although the E_1 and $E_1 + \Delta_1$ structures are merged into a broad structure. The broadening of the MCD structures due to Mn substitution is generally observed in II-VI based DMS,⁹ and can be attributed to the strong $sp-d$ hybridization. Note that the polarity of the MCD of $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ remains the same as that of GaAs. The effective g values of the GaAs at the E_1 edge were reported by Fujimori *et al.*¹⁰ as $g_{\text{eff}} = -1.63$. So g_{eff} of $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ should be negative also at the Λ CP. In DMS, polarity of g_{eff} depends on the polarity of $-(N_0\alpha - N_0\beta/4)$.¹¹ Because $N_0\alpha$ should be always positive,¹² our conclusion of the negative $N_0\beta$ is compatible with the negative g_{eff} .

The AF $p-d$ exchange in $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ presents a sharp contrast to the ferromagnetic $p-d$ exchange reported by Szczytko *et al.*¹² who studied the Zeeman splitting of heavily doped paramagnetic GaAs:Mn bulk crystals. We believe this discrepancy may be explained by taking into account variation of neutral (A^0) and ionized (A^-) Mn acceptors abundance with increasing Mn concentration. We recall that a neutral acceptor center is formed by substitutional Mn^{3+} (d^4) ion, which tightly binds an electron (yielding d^5 configuration) and then weakly (0.113 eV) binds a hole ($d^5 + h$ configuration).¹³ The hole is spin polarized and provides an additional, ferromagnetic exchange channel as pointed out in Ref. 12. This exchange path was suggested as responsible for F $p-d$ exchange reported for heavily doped (10^{17} – 10^{18} cm^{-3}) bulk samples.¹² On the other hand ionization of the hole leads to the ionized Mn acceptor A^- , which is equivalent to the Mn^{2+} (d^5) ion. For such center only AF $p-d$ exchange is possible, as established both experimentally¹⁴ and theoretically^{8,15,16} for Mn based II-VI DMS. For very diluted GaAs:Mn both A^0 and A^- centers were observed in the electron paramagnetic resonance (EPR) experiment.¹³ The EPR spectra of the paramagnetic bulk GaAs:Mn crystals used in Ref. 12 were compared with that of the ferromagnetic $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ ($x=0.005$) epitaxial film.¹⁷ At 3.5 K the bulk GaAs:Mn sample showed two strong lines corresponding to A^0 and A^- . The A^0 line disappears with increasing temperature, while the A^- line is observed up to 300 K. On the contrary, the EPR spectrum of the $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ ($x=0.005$) epilayer showed in the entire

temperature range only a signal corresponding to the A^- center. No A^0 signal was detected. Based on these observations we conclude that the concentration of neutral Mn acceptor centers A^0 in GaAs:Mn decreases with increasing Mn concentration, so for $x=0.005$ only A^- centers are left in the crystal. The reason for the disappearance of A^0 centers may be high hole concentration (10^{19} cm^{-3} for $x=0.005$ and 10^{20} cm^{-3} for $x=0.074$), which yields screening of the A^- attractive potential, so the hole can be hardly bound. We note that ionization of A^0 to A^- should supply the free holes, which contribute to the measured p -type conductivity of the epilayer. Effectively the absence of A^0 centers means that no F p - d exchange channels are available and one is left only with AF p - d exchange, typical for Mn^{2+} ions. This way the system of GaAs doped with Mn presents an interesting (and unique among DMS) case where concentration of A^0 centers (roughly inversely proportional to Mn concentration) controls the character of p - d exchange interaction. It changes from ferromagnetic at a very dilute limit to antiferromagnetic at a more concentrated range.

IV. CONCLUSIONS

In summary, we observed the strong enhancement of the magneto-optic effect at the critical points of the $\text{Ga}_{1-x}\text{Mn}_x\text{As}$. This indicates that $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ has a zinc-blende type band structure, and it shows the strong sp - d exchange interaction. The magnetic field dependence of the MCD signal at the critical point showed that ferromagnetism is an inherent property of the zinc-blende type $\text{Ga}_{1-x}\text{Mn}_x\text{As}$. From the polarities of the MCD structure, the antiferromagnetic p - d exchange interaction was indicated. Comparisons with the electron paramagnetic resonance data revealed a unique feature of $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ among DMS that the relative abundance of the neutral and ionized Mn acceptors changes the polarity of p - d exchange interaction.

We present magnetotransport properties, with emphasis on Hall effect, of a new class of III-V based magnetic $(\text{GaMnAs})/\text{nonmagnetic (AlAs)}$ semiconductor superlattices (SLs) grown by low-temperature molecular beam epitaxy. The SLs having relatively wide $(\text{GaMn})\text{As}$ layers ($\geq 70 \text{ \AA}$) are ferromagnetic at low temperatures, and their hole concentrations and Curie temperatures are estimated through the analysis of Hall measurements. The dependence of the magnetic and transport properties on the GaMnAs well width is discussed. © 1998 American Institute of Physics. [S0021-8979(98)21211-4]

I. INTRODUCTION

Diluted magnetic semiconductors (DMSs), containing a large fraction of magnetic ions in compound semiconductors, offer interesting opportunities to explore spin-related phenomena caused by the interaction of carriers and local magnetic moments. Recent progress in epitaxial growth techniques made it possible to grow III-V based DMSs, $(\text{InMn})\text{As}$,^{1,2} and $(\text{GaMn})\text{As}$.³⁻⁶ These III-V based DMSs, especially $(\text{GaMn})\text{As}$ which is based on the most widely used III-V semiconductor GaAs, provide new potential applications as well as unique opportunities for basic research, because carrier control is much easier in such III-V based systems than in traditional II-VI based DMSs.

We have successfully grown GaMnAs by low-temperature molecular beam epitaxy (LT-MBE) and have studied its magnetic, transport, and magneto-optic properties.^{3,4,7} Very recently, we have extended our study to III-V based magnetic quantum heterostructures, and have successfully grown magnetic $(\text{GaMnAs})/\text{nonmagnetic (AlAs)}$ semiconductor superlattices (SLs).^{8,9} The feasibility of preparing such magnetic semiconductor SLs will open up the unique possibility of coupling the spin-related phenomena with the well established band engineering in III-V semiconductors. In this article, we report magnetotransport properties, especially Hall effect, of the $(\text{Ga}_{1-x}\text{Mn}_x)\text{As}/\text{AlAs}$ magnetic semiconductor SLs.

II. EPITAXIAL GROWTH AND STRUCTURAL PROPERTIES

We have grown $(\text{Ga}_{1-x}\text{Mn}_x)\text{As}/\text{AlAs}$ SLs on semi-insulating (001) GaAs substrates by molecular beam epitaxy

(MBE) using solid sources of Ga, As, Mn, and Al. After growing a GaAs buffer layer at 600°C under normal growth conditions, the substrate temperature was cooled to 250°C . The As_4 flux was kept on throughout the growth. During the cooling process, the reflection high energy electron diffraction (RHEED) pattern changed from (2×4) to $c(4 \times 4)$. On this $c(4 \times 4)$ -(001) GaAs surface, an AlAs layer was first grown at a growth rate of $0.3 \mu\text{m/h}$, and then a $(\text{GaMn})\text{As}$ layer was grown at $0.5 \mu\text{m/h}$. This cycle was repeated 31 times to grow a SL structure at 250°C . The film-thicknesses of the $(\text{GaMn})\text{As}$ and AlAs were $45\text{--}120 \text{ \AA}$ and $30\text{--}68 \text{ \AA}$, respectively. The Mn content x in $(\text{Ga}_{1-x}\text{Mn}_x)\text{As}$ of the SLs studied here was $0.05\text{--}0.06$.

RHEED patterns during the growth of both $(\text{GaMn})\text{As}$ and AlAs were fairly streaky despite low-temperature growth. Clear twofold streaks were observed in the RHEED on the $(\text{GaMn})\text{As}$ surface, whereas almost no reconstruction was seen on the AlAs surface. Structural characterizations by x-ray diffraction and transmission electron microscopy showed that the SL structures were formed as intended with fairly abrupt interfaces.⁸

III. MAGNETOTRANSPORT PROPERTIES

Magnetization measurements using superconducting quantum interference device (SQUID) were done on the SLs, and it was found that the SLs with wider GaMnAs layers ($\geq 70 \text{ \AA}$) were ferromagnetic, whereas the SLs with narrower GaMnAs layers ($\leq 65 \text{ \AA}$) were not ferromagnetic but paramagnetic even at 2 K. In all the ferromagnetic SLs, the easy axis of magnetization lies in-plane, like the thick ($\sim 1 \mu\text{m}$) GaMnAs films.³ The magnetic properties of $(\text{GaMn})\text{As}$ and related heterostructures can be studied through transport measurements, since all the samples show p -type conduction. Holes are supplied by Mn acceptors with which Ga sites in the GaAs zincblende structure are replaced.¹⁰ Since the ferromagnetic order of $(\text{InMn})\text{As}$ is

^{a)}Also at: PRESTO(Sakigake-21), Japan Science & Technology Corporation, 4-1-8 Honcho, Kawaguchi 332, Japan; electronic mail: masasaki@ee.t.u.-tokyo.ac.jp, t: 011-81-3-3812-2111 ext 6729, f: 011-81-3-3816-4996

FIG. 1. Temperature dependence of the sheet resistance of the SLs; (a) sample A: (GaMn)As(70 Å)/AlAs(30 Å), (b) sample B (GaMn)As(120 Å)/AlAs(68 Å).

considered to be induced by holes,^{2,11} it is interesting to study the transport properties in such GaMnAs magnetic heterostructures.

First we have done transport measurements on the ferromagnetic (GaMn)As/AlAs SLs with relatively wider well widths (≥ 70 Å). The measurements were performed at various temperatures (2–300 K) on photolithographically patterned Hall bars with a width and a length of 200 μm and 1.3 mm, respectively. We present the results of two SL samples; one is sample A [(Ga_{0.95}Mn_{0.05})As(70 Å)/AlAs(30 Å)], and the other is sample B [(Ga_{0.94}Mn_{0.06})As(120 Å)/AlAs(68 Å)]. Magneto-optic spectra using magnetic circular dichroism (MCD) on these SLs have shown the clear evidence for quantum confinement effect and the formation of subbands.⁸ Figure 1 shows the temperature dependence of their sheet resistivity ρ_{sheet} . Sample A shows a nonmetallic (semiconducting) behavior, where the resistance increases with lowering temperature. On the other hand, the behavior of sample B is more like a metallic conduction, where the resistance is almost constant below 50 K. Since the characteristics of thick (GaMn)As films (~ 1 μm) with similar Mn content was similar to that of sample B, the difference between the two SL samples can be attributed to the difference of the GaMnAs well width. Also, there is a broad hump for sample B, which roughly corresponds to the Curie temperature T_C (~ 60 K). Such a hump is not observed in sample A, whose T_C is around 46 K, as will be estimated by our magnetotransport study below.

Next, we measured Hall effect on these ferromagnetic SLs. In general, the Hall resistivity of magnetic materials is expressed as $\rho_{\text{Hall}} = R_0 B + R_s M$, where R_0 is the normal Hall coefficient, B the magnetic flux density, R_s the extraordinary Hall coefficient, and M the magnetization. The first term represents the ordinary Hall effect caused by Lorentz force, and the second term does the extraordinary Hall effect (EHE) caused by the anisotropic scattering between carriers and local moments. When the materials are ferromagnetic (at low temperature), one can neglect the first term because the second term is much larger; $\rho_{\text{Hall}} = R_0 B$. On the other hand, at

FIG. 2. (a) Hall effect of sample A (GaMn)As(70 Å)/AlAs(30 Å) SL at relatively low temperature range. (b) Temperature dependence of Hall coefficient R_H of sample A. The horizontal axis is $\rho_{\text{sheet}}/(T-T_C)$, where T_C is fitted as 46 K.

high temperature where the materials are paramagnetic, the Hall coefficient $R_H (= \rho_{\text{Hall}}/B)$ is given by

$$R_H = R_0 + \frac{c \rho_{\text{sheet}}}{\mu_0} \frac{C}{(T - T_C)} \quad (1)$$

because the magnetization M is expressed as $M = \chi H$, where χ is the magnetic susceptibility which follows the Curie-Weiss law. Here C is the Curie constant and R_s is represented as $c \rho_{\text{sheet}}$ (c : constant) for simplicity.

Figure 2(a) shows the Hall effect of sample A at low temperature range. The clear ferromagnetic behavior was observed at low temperature (< 46 K). Here only very little hysteresis loops appeared, because the easy axis of magnetization lies in-plane and the field is applied perpendicular along the hard axis. The Hall resistivity is proportional to the magnetization in ferromagnetic materials as describe above, $\rho_{\text{Hall}}/\rho_{\text{sheet}} = A M_s$ (A is constant). Then one can calculate the spontaneous magnetization M_s near the Curie temperature (low temperature range) by making the Arrott plot, $(\rho_{\text{Hall}}/\rho_{\text{sheet}})^2$ versus $B/(\rho_{\text{Hall}}/\rho_{\text{sheet}})$. Thus we have estimated the Curie temperature T_C of sample A to be 49 K.

On the other hand, from the temperature dependence of the Hall coefficient R_H at high temperature range, we can

FIG. 3. Magnetic field dependence of Hall resistivity ρ_{Hall} of sample A measured at 10 K.

also estimate T_C and R_0 . We measured R_H at various temperatures and made the plot of $R_H (= \rho_{\text{Hall}}/B)$ near zero field versus $\rho_{\text{sheet}}/(T - T_C)$, as shown in Fig. 2(b), which is linear as expected from the Eq. (1). In making this plot, the value of T_C was best fitted to be 46 K, in good agreement with the estimation by the Arrott plot. Also, R_0 was estimated from Fig. 2(b) and the hole concentration p of this sample is estimated to be $1.3 \times 10^{13} \text{ cm}^{-2}$ per (GaMn)As quantum well.

Then we have done the Hall measurements of this sample under higher magnetic field (up to 12 T) at lower temperature (10 K), as shown in Fig. 3. The negative slope of Hall resistance at higher field is due to the contribution of resistivity ρ_{sheet} through $R_s = c\rho_{\text{sheet}}$. In fact, very large negative magnetoresistance (MR) was observed at high field in this sample. Assuming that the magnetization at 10 K saturates at sufficiently low field and becomes constant at high field, we can estimate R_0 , i.e., the hole concentration p , by excluding the negative MR contribution of the $\rho_{\text{sheet}}(B)$ data from the $\rho_{\text{Hall}}(B)$ data and by estimating the remaining slope of $\rho_{\text{Hall}}(B)$ at high field ($B > 10$ T). In this way, the hole concentration p of sample A is estimated to be $2.3 \times 10^{13} \text{ cm}^{-2}$ per (GaMn)As quantum well at 10 K. Although the estimation of carrier concentration of ferromagnetic samples is generally very difficult due to the strong contribution of extraordinary Hall effect, we have analyzed the magnetotransport data and have estimated it by low field and high field measurements.

We have also done the same magnetotransport measurements of sample B with wider (GaMn)As quantum wells. From the Arrott plot at low temperature range, T_C was estimated to be 63 K. From the temperature dependence of the Hall coefficient at high temperature range, T_C and hole concentration p of this sample is estimated to be also 63 K and $6.2 \times 10^{14} \text{ cm}^{-2}$ per (GaMn)As layer. Both T_C and p of sample B are higher than those of sample A.

Although both samples A and B are ferromagnetic at low temperatures, SQUID measurements revealed that no ferromagnetic phase appeared in the SL samples whose well width is less than 70 Å even at low temperature ($T = 2$ K).

The SL samples with no ferromagnetic order became high resistive at low temperature and transport measurements were difficult. This is probably because carriers are localized due to some structural fluctuations such as interface roughness. The fluctuations of the quantized energy due to interface roughness becomes rapidly large with the decrease of the quantum well width. These experimental facts strongly suggest that the ferromagnetic order in (GaMn)As is induced by carriers (holes), and the hole concentration of sample A ($1 - 2 \times 10^{13} \text{ cm}^{-2}$) gives the critical value for the ferromagnetic order in (GaMn)As quantum wells.

IV. SUMMARY

We have shown the magnetotransport properties, with emphasis on Hall effect, of a new class of III-V based magnetic (GaMn)As/nonmagnetic (AlAs) semiconductor superlattices (SLs). The SLs having relatively wide (GaMn)As layers (≥ 70 Å) are ferromagnetic at low temperature, and their hole concentrations and Curie temperatures are estimated. The hole concentrations of the (GaMn)As(70 Å)/AlAs(30 Å) SL and the (GaMn)As(120 Å)/AlAs(68 Å) SL are estimated to be $1.3 - 2.3 \times 10^{13} \text{ cm}^{-2}$ and $6.23 \times 10^{14} \text{ cm}^{-2}$ per (GaMn)As layer, and the Curie temperatures are estimated to be 46 K and 63 K, respectively.

Magnetic semiconductor superlattices consisting of x monolayers of ZnTe alternated with y monolayers of MnTe $[(\text{ZnTe})_x(\text{MnTe})_y]$ have been grown in the zinc-blende structure by molecular beam epitaxy. For relative thin ZnTe nonmagnetic interlayers ($3 \leq x \leq 6$), neutron diffraction data show long range order within the MnTe layers and also an interlayer magnetic coupling across the semiconducting ZnTe interlayer extending over multiple bilayers. For the $x = 5$, $y = 10$; and $x = 4$, 5 , $y = 20$ superlattices at low temperature (10 K), the spins in adjacent MnTe layers couple in an inphase antiferromagnetic structure with identical spin orientations in all MnTe layers. As the temperature is raised, this ordering slowly transforms into an antiphase coupling in which alternate MnTe layers have spin directions reversed. For increasing ZnTe layer thickness, a systematic reduction in the magnetic correlation range is observed, with the correlation range reducing to approximately one MnTe layer for $x = 6$ and 7. © 1998 American Institute of Physics. I. INTRODUCTION

Magnetic semiconductor II–VI compounds grown as single crystal epitaxial structures by molecular beam epitaxy (MBE) techniques exhibit a number of unique magnetic phenomena associated with their crystal structure and exchange interactions.^{1–4} In this article, we report results on superlattices consisting of alternate layers of MnTe and nonmagnetic ZnTe [i.e., $[\text{ZnTe}|\text{MnTe}]$] that exhibit long range order within the magnetic layers, and for thin ZnTe interlayers also show magnetic coupling along the growth axis extending over several bilayers.

These MBE structures crystallize in the cubic zinc-blende (ZB) crystal structure in which the antiferromagnetic (AFM) interactions are typically close idealizations of the Heisenberg fcc model. The coupling is dominated by nearest neighbor (NN) superexchange between magnetic cations that are arranged in a tetrahedron with the mediating anion sited at the center. Because of exchange paths that involve more than one anion, the next nearest neighbor (NNN) exchange is typically reduced^{2,5} by a factor of 5 to 10. The dominance of NN AFM coupling and the tetrahedral atomic arrangement leads to near perfect exchange frustration in the intrinsic ZB AFM structure. This frustration can be removed by selective dilution, strain, or local atomic distortions.

In the $[\text{ZnTe}|\text{MnTe}]$ superlattices, the approximately 4% lattice parameter mismatch strain between layers effectively eliminates the tetrahedral spin frustration. The result is a long range ordering of the MnTe layers in a three dimensional type III AFM structure that is consistent with the dominant NN exchange and a weaker but antiferromagnetic NNN exchange. There are three possible orthogonal domain

orientations in this structure; however the epitaxial strain energies favor the single domain for which the AFM doubling of the unit cell is along the superlattice growth direction [001]. This domain preference² is temperature dependent with about 67% of the domains of [001] orientation at low temperature rising to near 100% [001] domains near T_N .

It should be noted that in bulk form MnTe crystallizes in the nonspin-frustrated NiAs structure; however it can be forced into the cubic zinc-blende (ZB) structure by alloying with a nonmagnetic constituent such as ZnTe or CdTe. In these cases, the ZB cell can be stabilized for Mn concentrations as high as 70% and the Mn spins show moderate-range antiferromagnetic correlations extending out to 30–70 Å, but no long-range order.^{2,3} MBE growth techniques extend the range of stability of the ZB structure up to 100% MnTe.

II. SUPERLATTICE MAGNETIC SCATTERING

Superlattices $[(\text{ZnTe})_x(\text{MnTe})_y]_n$ have been prepared by MBE on (001) GaAs substrates over a significant range of MnTe and ZnTe layer thicknesses. For moderately thick ZnTe interlayers (e.g., $x = 18$), long-range AFM order exists within each MnTe layer. However, neutron scattering results show no evidence of coupling between the spin structures in adjacent Mn layers.

In sharp contrast to these results on superlattices with thick ZnTe nonmagnetic interlayers, recent neutron diffraction studies on superlattices with relatively thin ZnTe interlayers (e.g., $3 \leq x \leq 7$) show interlayer exchange couplings that extend across multiple bilayers (for $x = 3, 4$, and 5). This result was quite unexpected due to the short range nature of conventional superexchange interactions.

The neutron diffraction data were taken at the University of Missouri Research Reactor using a triple axis spectrom-

eter with an analyzer set for elastic scattering to reduce unwanted background signals. Neutrons with $E=14.7$ meV from a (002) pyrolytic graphite focusing monochromator were used with a flat analyzer and $40'-20'-20'-40'$ Soler slit collimation. This gave a q resolution for longitudinal scans of 0.018 \AA^{-1} . Longitudinal [001] scans through nuclear structure peak positions (see inset of Fig. 1) exhibited multiple bilayer harmonics that were essentially resolution limited in width, reflecting the excellent crystal quality, and a structural coherence essentially equal to the sample thickness. Transverse scans were also made through both nuclear and magnetic principal peaks to confirm the in-plane ordering. The thickness of a bilayer, Γ in Angstroms, that was obtained from the separation of the superlattice structural harmonic peaks ($\Delta Q = 2\pi/\Gamma$) was in satisfactory agreement with that determined from the growth parameters. However, the bilayer spacings obtained from the magnetic superlattice reflections was generally larger by several percent than that obtained from the nuclear harmonics. This discrepancy is currently not understood.

The type III antiferromagnetic spin ordering gives rise to purely magnetic peaks with coordinates $\{(0,k,n/2), \text{ where } n=2\ell+1\}$ corresponding to the single domain for which the doubling of the unit cell is along the growth axis. Longitudinal scans through the $(0,1,\frac{1}{2})$ AFM peak for a $[(\text{ZnTe})_5(\text{MnTe})_{10}]$ superlattice in Fig. 1 at low tempera-

FIG. 2. Scattered intensity at the AFM reflection in a $[(\text{ZnTe})_4(\text{MnTe})_{20}]$ superlattice. In-phase and antiphase magnetic peak positions are indicated by the vertical dotted and dot-dashed lines as in Fig. 1.

ture reveal a fundamental magnetic peak and harmonic sidebands, thus demonstrating conclusively the existence of antiferromagnetic coupling extending over multiple bilayer periods. The scattering data further show the existence of two types of interlayer long range coupling, and a gradual transfer of intensity (net magnetization) from one type to the other as temperature is increased. Each MnTe layer retains the type III AFM spin configuration; however, in the first coupling scheme (in-phase), the spin direction on each site of the first atomic plane of adjacent MnTe layers is identical. In the second coupling arrangement (antiphase), the spin directions on each site of the first atomic plane are reversed between adjacent MnTe layers. The in-phase magnetic structure has the same repeat sequence as the atomic structure and results in the formation of a central magnetic peak and bilayer harmonics (indicated by the outer pair of vertical dotted lines in the figure) each with the same spacing ($\Delta Q = 2\pi/\Gamma$) as the structural peaks. The antiphase structure introduces a new set of bilayer harmonics, into the structure that are located midway between the in-phase structure harmonics as shown by the inner set of dot-dashed lines in the figure. The occurrence of both AFM structures was reproducible and also observed in superlattices from a different series,⁶ $[(\text{ZnTe})_x(\text{MnTe})_{20}]$ as shown for $x=4$ in Fig. 2. Only the in-phase structure was observed, however, in the $[(\text{ZnTe})_4(\text{MnTe})_{10}]$ superlattice.

The magnetic intensity in Figs. 1 and 2 is proportional to the square of a Mn order parameter. Figure 3 shows separately the temperature dependence of the order parameters for the "in-phase" and the "antiphase" antiferromagnetic states for the $x=5, y=10$ superlattice. The in-phase compo-

FIG. 3. Temperature dependence of the in-phase and antiphase magnetic domain intensities and the total magnetic intensity as a function of temperature. The solid line is a fit to the Brillouin function for $S=5/2$. The dotted lines are guides to the eye.

ment represents the square root of the integrated intensity of the central peak plus its two side bands separated by $2\Delta Q$, while the antiphase order is the square root of the sum of the integrated intensities of only the two intervening peaks separated by ΔQ . The total order parameter is derived from the square root of the total magnetic intensity and is well represented by a $S=5/2$ Brillouin function. The agreement with the Brillouin mean field result is worse if applied to the sum of the individual in-phase and antiphase magnetizations, which is consistent with the assumed uncorrelated nature of the two types of antiferromagnetic orderings. The results in Fig. 2 clearly show that the in-phase order predominates at low temperature, but, as the temperature is raised, it is gradually replaced by the antiphase ordering before both vanish at a common Néel temperature near 75 K. The 75 K value for the Néel temperature was essentially identical for all the superlattices studied. It should be remarked that the behavior of the two antiferromagnetic orderings reflects a change of the number of Mn spins involved in each phase with temperature; however the temperature dependence of the full Mn sublattice moment is mean field as confirmed by the Brillouin fit to the total magnetic intensity. Whether the temperature dependence of the two AFM structures is related to the temperature dependent relative population of domains parallel to and perpendicular to the growth axis is not known.

The coherence range of the magnetic order has been obtained from the width in \AA^{-1} of the principal magnetic peak after deconvoluting the resolution width. The net width ΔQ

FIG. 4. Magnetic coherence lengths obtained from the width of the principal magnetic peaks for the compositions studied. Results are shown for two temperatures below the 75 K Néel temperature.

$=2\pi/\xi$ where ξ is the coherence range in \AA . Coherence ranges for the series of superlattices with 5, 6, and 7 ML ZnTe layers are shown in Fig. 4 for the series with MnTe thickness of 10 ML. Essentially the same results were obtained for the $y=20$ ML series that are also given in the figure. The results show that the coherence range drops with increasing thickness of the diamagnetic ZnTe layer and also shows a weaker dependence on temperature. For the $[\text{ZnTe}_5\text{MnTe}_{10}]$ superlattice, the correlation range at 10 K corresponds to magnetic order coherent over approximately 70 ML (nearly five bilayers), and it drops to about 35 ML (only somewhat more than 1 bilayer) for the $[\text{ZnTe}_7\text{MnTe}_{20}]$ superlattice, indicating that long range order is destroyed by ZnTe interlayer thicknesses of 6 to 7 ML. A precise determination of ξ in the samples with $(x=6,7)$ ZnTe layers is complicated by the partially unresolved main peak and bilayer harmonics.

We have investigated the magnetic properties of $\text{Ga}_{1-x}\text{Mn}_x\text{Se}$, which represent a new class of diluted magnetic semiconductors based on a III-VI semiconductor. These are layered materials; however the local environment is tetrahedral as in the II-VI materials. In contrast to the II-VI semiconductors, the Mn substitutional atoms have direct bonds to three Se atoms and to either a Ga or Mn atom. This leads to a complex temperature dependent magnetization. In fields of 100 G and below, a broad peak is observed in the magnetization centered at 160 K. In addition, a sharp change in magnetization is observed at 119 K. In a field of 100 G, the peak has a magnitude of 3×10^{-5} emu/g above the background of 7×10^{-5} emu/g. With increasing magnetic fields, these features are broadened which is suggestive of some type of short-range antiferromagnetic ordering. At 5 K we observe a magnetization which increases linearly with field up to 6 T similar to the Van Vleck paramagnetic behavior observed in the Fe substituted II-VI semiconductors. © 1998 American Institute of Physics. [S0021-8979(98)44011-8]

I. INTRODUCTION

The new class of III-VI diluted magnetic semiconductors (III-VI DMS) include systems of the form $\text{A}_{1-x}^{\text{III}}\text{M}_x^{\text{VI}}$, where $\text{A}_{1-x}^{\text{III}}\text{B}^{\text{VI}}$ is a III-VI semiconductor and M is a transition metal ion. The III-VI semiconductors GaSe ,¹⁻⁴ InSe ,^{1,5,6} GaTe ,⁷ and GaS (Ref. 8) have received considerable interest in the last few years because they have remarkable nonlinear optical properties and are promising materials for photoelectronic applications. Although Mn has been incorporated into GaSe up to ~ 1 at. % nominal level (in samples grown from the melt), this work is focused on photoluminescence,^{3,9,10} photoconductivity,^{5,10} Hall effect,³ electron spin resonance,^{11,12} and deep-level transient spectroscopy measurements.³ No magnetization studies have been reported.

Like the II-VI DMS,¹³ substitutional magnetic ions in the III-VI DMS are in a tetrahedral environment. However, in sharp contrast to the II-VI DMS, the III-VI semiconducting host is two dimensional (Fig. 1). Each $\text{Ga}_{1-x}\text{Mn}_x\text{Se}$ layer is comprised of a top two-dimensional layer of Se ions, two middle layers of Ga ions, and a bottom layer of Se ions as shown in Fig. 1(a). Within each four atom thick layer, the bonds are covalent.¹⁴ The weak van der Waals bonding between the stacked four atom thick layers further enhances the two-dimensional nature of this crystal.¹⁴

Because each Ga ion has three neighboring Se ions as well as another Ga ion, substitutional magnetic ions would experience a host of different local environments. In III-VI DMS, directly bonded Mn-Mn pairs [shown as a dotted line in Fig. 1(a)] are expected which opens a channel for a direct

exchange between magnetic ions. In addition, both Mn-Se-Mn superexchange interactions (common in II-VI DMS), and Mn-Ga-Se-Mn pairings are also possible [Figs. 1(a) and 1(b)].

In this article we present magnetization measurements taken on bulk $\text{Ga}_{1-x}\text{Mn}_x\text{Se}$. The crystal structure of $\text{Ga}_{1-x}\text{Mn}_x\text{Se}$ is analyzed in terms of several distinct configurations of the magnetic ions within the III-VI lattice structure leading to a complex magnetic behavior.

II. EXPERIMENTAL DETAILS

Single-crystalline $\text{Ga}_{1-x}\text{Mn}_x\text{Se}$ samples were taken from a boule with a nominal concentration of $x=0.05$. Typically, samples grown by the vertical Bridgman method yield actual concentrations less than the nominal value. Atomic absorption spectroscopy (AAS) was performed yielding a value for the concentration of $x=0.012$. It is expected that the solubility limit for Mn in GaSe is higher than the amount of Mn incorporated into this sample and that higher concentrations will be achieved as the crystal growing technology for this system develops further.

Magnetic measurements were made between 1.5 and 324 K in fields up to 6 T using a commercial superconducting quantum interference device (SQUID) magnetometer. The diamagnetic susceptibility -2.0×10^{-7} emu/g G for GaSe has been subtracted from the data.¹⁵

III. EXPERIMENTAL RESULTS AND DISCUSSION

$\text{Ga}_{1-x}\text{Mn}_x\text{Se}$ exhibits magnetic behavior that is significantly different from that observed in II-VI DMS. Magnetization versus temperature measurements taken in a 0.01, 0.05, 0.1, 1, and 6 T field are shown in Fig. 2. Focusing on

^{a)}Electronic mail: tpekarek@gw.unf.edu

FIG. 1. Crystal structure for $\text{Ga}_{1-x}\text{Mn}_x\text{Se}$. The big solid circles are the Ga lattice sites in GaSe or the substitutional Mn lattice sites in $\text{Ga}_{1-x}\text{Mn}_x\text{Se}$. The small squares are the Se lattice sites. (a) Cross section of a four atom thick layer. The tetrahedral environment of the Ga or Mn lattice sites is emphasized with three neighboring Se ions as well as another Ga or Mn ion. The direct Mn-Mn bond is shown by the bold dotted line. The bold solid line emphasizes the bonds in a Mn-Se-Mn pair. A Mn-Ga-Se-Mn pair can be seen where the bold dotted line is the bond between the Ga and the first Mn ions and the bold solid lines then completes the Ga-Se-Mn bonds. (b) Top view of a single four atom thick layer. The top and bottom Mn ions are in a vertical line as are the Se ions. The bold solid lines are the bonds in the Mn-Se-Mn pair. The pair Mn~Se-Mn (where ~ denotes a van der Waals bond between layers) would have a van der Waals bond between the Mn (in the four atom thick layer shown) and a Se ion directly above followed by a covalent bond to a Mn ion located at position A. The second layer would then be offset to the right by one half of the hexagon width.

the 0.01 T data, the key features are a broad peak between 120 and 195 K with an apex at 160 K and a sharp change in magnetization at 119 K. With increasing field, the peak appears to broaden and shift to lower temperatures, until it is barely visible above a rising background signal by 6 T. The sharp drop at 119 K is also rapidly broadened by the magnetic field.

Given the observed broadening of these features in increasing magnetic fields, the expected antiferromagnetic interactions between the magnetic ions, and the two-dimensional crystal structure, our data is suggestive of short-range two-dimensional antiferromagnetic ordering.¹⁶ The sharp drop in magnetization at 119 K could then be interpreted as a transition to three-dimensional order as the inter-layer coupling becomes important. Given the low concentration of magnetic ions ($x=0.012$) as well as the increasing low temperature magnetization discussed below, it is likely that any order is short-range.

We also cannot rule out the possibility that microcrystals of MnSe exist within our samples and are producing the observed magnetization signal. We note that the Néel temperature of thin films of MnSe was found to be 115 K by

FIG. 2. Magnetization vs temperature for $\text{Ga}_{1-x}\text{Mn}_x\text{Se}$ in a 0.0100, 0.0500, 0.1, 1, or 6 T field. The diamagnetic contribution due to GaSe has been subtracted. The solid vertical bar at 210 K in each graph is 3×10^{-5} emu/g tall to aid in a quick comparison of scales.

Samarth *et al.*¹⁷ which is very close to the observed sharp feature at 119 K.

However, Ishchenko and co-workers^{11,12} found that the bulk of the manganese in their GaSe:Mn crystals did go in as substitutional Mn^{2+} ions at the gallium lattice sites and have the ϵ -GaSe layer structure.¹⁴ The ϵ -GaSe layer structure has a two-layer basis. The top layer is offset to the right by one half of the hexagon width [i.e., one pair of Ga/Mn lattice sites is directly above position A in Fig. 1(b)]. Lee *et al.* also found the ϵ -GaSe structure for their GaSe:Mn crystals.¹⁰ Shigetomi argued from conductivity measurements that a small fraction of their Mn was located in the interstices or between the layers of GaSe.³

Turning now to the low temperature behavior of these samples, we show in Fig. 3(a) the temperature dependence of the magnetization in $\text{Ga}_{1-x}\text{Mn}_x\text{Se}$ at 1 T between 5 and 325 K. As can be seen, there is a background magnetization that monotonically increases, in addition to the broad peak discussed above. The background rises above the peak at low temperatures and is rapidly increasing.

To further investigate this background we show in Fig. 3(b) data on magnetization versus field taken at 5 K, which is well below the broad peak discussed above. As can be seen the increase in magnetization is nearly linear in magnetic field with $M/H=6.2 \times 10^{-7}$ emu/g G. This is much weaker than a $S=5/2$ Brillouin function represented in the figure as a dotted and dashed lines for $x=2 \times 10^{-4}$ and $x=0.012$, respectively. Further, even at 6 T there is no evidence that the magnetization is saturating. The linear field dependence is similar to that seen in Fe based II-VI semiconductors. In that case it is attributed to Van Vleck paramagnetism.¹⁸

FIG. 3. The magnetization data for $\text{Ga}_{1-x}\text{Mn}_x\text{Se}$ are shown by solid circles. (a) Magnetization vs temperature in a 1 T field. (b) Magnetization versus field at 5 K. The dotted and dashed lines are a $S = 5/2$ Brillouin response for $x = 2 \times 10^{-4}$ and $x = 0.012$, respectively. The diamagnetic contribution due to GaSe has been subtracted from the data.

Some of the magnetic behavior of the II-VI DMS has been successfully understood assuming that the transition metal ions are randomly incorporated into the host lattice. The theory was then developed taking into consideration the fraction of magnetic ions incorporated as singlets, doublets, triplets, etc., assuming only the shortest-range interactions.¹³ Looking within a single layer in Fig. 1 we see that if Mn substitutionally replaces Ga in this material, then the probability p of a Mn being a singlet is $p = (1 - x)$.¹³ There is one Mn-Mn neighbor [$p = x(1 - x)$], six Mn-Se-Mn neighbors [$p = 6x(1 - x)$], and six Mn-Ga-Se-Mn neighbors [$p = 6x(1 - x)$] (note that there are two equivalent exchange channels between the two Mn ions). If we also consider interlayer couplings, with one Mn ion in each layer there are three Mn~Se-Mn neighbors, three Mn-Ga~Se-Mn neighbors, and three Mn~Se-Ga-Mn neighbors (note that ~ denotes a van der Waals bond between layers).

For a concentration of $x = 0.012$ this leads to 1% of the Mn atoms having direct bonds with a second Mn atom. We expect this interaction to be much stronger than the superexchange interactions and would tentatively ascribe the peak at 160 K to these pairs and larger clusters. We note that the

saturation magnetization of the directly bonded Mn with $S = 5/2$ spins would be roughly 0.025 emu/g. The fact that this number is a factor of 700 larger than the observed peak height, might be expected if the peak arises from antiferromagnetic ordering of the Mn-Mn pairs. The remaining 99% of the Mn atoms, which are not involved in direct bonds with a second Mn atom, would then contribute to the low temperature behavior.

IV. CONCLUSIONS

Mn substituted III-VI semiconductors represent a new class of diluted magnetic semiconductors. We have studied $\text{Ga}_{1-x}\text{Mn}_x\text{Se}$ and found a magnetization peak at 160 K that is not observed in the II-VI DMS. We tentatively ascribe this peak to direct Mn-Mn bonds in this material. In addition, we find a linear magnetization as a function of field at low temperatures which is reminiscent of the Fe based II-VI materials.

A novel technique for the visualization of antiferromagnetic domains making use of second harmonic generation is used to study the easy-plane antiferromagnet YMnO_3 . Domain states characterized by small, medium, or large domains are observed. Switching from one state to another can be achieved by a heat treatment *above* T_N and subsequent cooling *below* T_N . Contributions to the mechanism of this unusual behavior of domains are discussed. © 1998 American Institute of Physics. [S0021-8979(98)21411-3]

Domains, domain walls, and their behavior as a function of external fields and material parameters is one of the most fundamental and technologically important problems of magnetic solids. The configurational details of domains in substances with a spontaneous magnetization, as arising from the competition of various contributions to the total energy, are discussed in many articles,¹ and a large number of experimental methods for the investigation of ferro- or ferrimagnetic domains have been developed.²⁻⁴ There are, however, merely a few publications on the formation of domains and domain walls in antiferromagnets.^{1,5,6} One of the reasons for this is the very limited number of experimental techniques for the visualization of antiferromagnetic (AFM) domains.⁷

In this article, we report the study of the afm domain structure and its variation with temperature in YMnO_3 using a recently developed method of nonlinear optical spectroscopy.⁷⁻⁹ Domains in YMnO_3 show a behavior drastically different from that in any other known AFM crystal. We have found that by suitable annealing *above* T_N samples can be switched into different states characterized by small, medium, or large domains *below* T_N .

At low temperature, hexagonal YMnO_3 is antiferromagnetic and ferroelectric. The crystal structure below the ferroelectric Curie temperature $T_C = 930$ K is described by the noncentrosymmetric point group $6mm$.¹⁰ The magnetic properties of YMnO_3 arise from the $\text{Mn}^{3+}(3d^4)$ ions in the high-spin state, $S = 2$. Below $T_N = 74$ K, the spins of the six Mn^{3+} ions in the unit cell are ordered antiferromagnetically in a triangular structure with all spins perpendicular to the polar axis. The corresponding magnetic point group is $6mm$.^{11,12}

Above T_N , second harmonic (SH) generation in YMnO_3 is allowed in the electric-dipole approximation due to the time-invariant (*i* type) susceptibility $\chi_{ijk}(i)$. This contribution, which is solely related to the symmetry of the crystal lattice, vanishes for propagation of light along the C_6 axis ($\mathbf{k} \parallel \mathbf{z}$). Below T_N , electric-dipole contributions to SH are

also allowed due to the time-noninvariant (*c* type) susceptibility $\chi_{ijk}(c)$,¹³ which is related to the magnetic structure of the crystal

$$P_x(2\omega) = \epsilon_0 \chi_{xxx}(c) [E_x^2(\omega) - E_y^2(\omega)], \quad (1)$$

$$P_y(2\omega) = -2\epsilon_0 \chi_{xxx}(c) E_x(\omega) E_y(\omega). \quad (2)$$

The nonlinear polarizations $P_x(2\omega)$ and $P_y(2\omega)$ change phase by 180° when passing from one AFM domain to another, which is accompanied by a sign reversal of any AFM order parameter and thus of $\chi_{xxx}(c)$.

Flux-grown (0001) single crystals, both as-grown and polished, with a thickness of 0.1–0.5 mm along the (0001) axis and lateral dimensions 1–4 mm were used in the experiments. Optical absorption spectra were found to be in agreement with previously reported data.¹⁴ In order to find the SH energy most suitable for imaging of domains, the SH spectrum was measured at low temperature (Fig. 1). In accordance with Eqs. (1) and (2), there was no difference in the spectra for right and left circularly polarized light. As expected, no SH was observed for $T > T_N$.

FIG. 1. SH spectrum of YMnO_3 at $T = 8$ K for light propagating along the optical axis $C_6(z)$. The spectra with right and left circularly polarized light are identical. The inset shows the temperature dependence of the SH signal at 2.461 eV.

^{a)}Electronic mail: fiebig@ap.t.u-tokyo.ac.jp

FIG. 2. Image of 180° AFM domain in a polished sample at $T = 8$ K showing the interchange of the contrast between domains by shifting the phase between time-invariant and time-noninvariant SH contributions by 180° . This large domain state can be obtained via path 5 in Fig. 4.

Recently, a new optical method for topography of AFM domains was introduced. It was shown that visualization of 180° AFM domains is possible when there is interference of c - and i -type contributions to the SH.⁷⁻⁹ If both contributions are (1) *intrinsically* present and (2) of the same order of magnitude, domains can be visualized just by projecting the SH light emitted from the sample on a CCD camera, where the phase shift between the c - and i -type light field is converted into an intensity contrast. Due to restriction (1), this method is suitable only for substances with a favorable point symmetry and only in those spectral regions which meet restriction (2). In most substances, the conditions (1) and (2) are not met, and in order to visualize the domain structure the time-noninvariant SH signal originating in the magnetic ordering of the crystal has to be superimposed with an *externally* generated time-invariant SH light field, e.g., from a crystalline quartz plate. By proper adjustment of phases and amplitudes of the c - and the i -type light fields, their interference on the camera can lead to a high contrast between the brightness of different domains. With circularly polarized light, the phase of the reference light field can be controlled by rotating the quartz plate whereas the amplitude can be adjusted by making use of optical filters and spectral oscillations of the SH intensity from the quartz plate known as Maker fringes.¹⁵ Details of this novel technique and the experimental setup are given in Ref. 7. The information on the spatial distribution of domains is contained in the phase and the amplitude of the c -type SH field from the sample, which is different for domains with different orientations of the AFM order parameter. By the invention of the *external ref-*

FIG. 3. Three images of small (a), medium (b), and large (c) domain states in an as-grown sample. Access to each of these states can be achieved via heat treatment processes shown in Fig. 4.

erence, SH domain topography can now be applied to *any* antiferromagnet exhibiting a sufficiently strong time-noninvariant contribution to the SH signal.

Figure 2 shows two images of AFM domains in a polished sample at $T = 8$ K. Dark and bright regions correspond to the respective 180° domains. Instead of straight or slightly curved planes which are typical for most antiferromagnets,^{3,16-18} the walls in YMnO_3 look like patchwork with some small domains surviving inside larger ones. The contrast in the two images is interchanged by changing the phase of the reference field from the quartz plate by π . Images with a contrast of 3:1 up to 20:1 between neighboring domains are obtained with exposure times of 3–5 min. Without external SH reference, the contrast between domains vanishes, although domain walls remain visible.

No changes of the domain structure were observed when the temperature was varied below T_N . However, striking changes occurred after heating and cooling the sample through T_N . Figure 3 shows three images of AFM domains in an as-grown sample, which are characterized by small- (a), medium- (b), and large-domain states (c). Here we refer to the average size of the domains throughout the whole sample. Each cycle of the sample through T_N resulted in a

FIG. 4. Diagram showing thermal routes to different AFM states, characterized by domains of small, medium, and large size. Distribution functions of domain size for each state are shown schematically.

different domain pattern even if the distribution function did not change. Cooling rates from 1 to 20 K/min and dwell times of 0–20 min at the annealing temperature $T_a > T_N$ were found to have no influence on the achievement of different domain states. In the small-domain state, the dimension of domains was about 20–40 μm . Smaller domains ($< 10 \mu\text{m}$) which were not resolved by the optical system might have been present. In the large-domain state, the average dimension of domains was larger by an order of magnitude with some of the domains extending over the entire sample. No pronounced difference was noticed between polished and as-grown samples. Domain patterns are different in detail on opposite sides of the sample, but they both belong to the same domain state.

The AFM domain patterns look different in large- and small-domain states after each cycle through T_N . This indicates that memory effects are absent or very small. Furthermore it disproves correlations to ferroelectric domains.¹⁹ YMnO_3 exhibits a rather large electric coercive field $E_C = 2.5 \times 10^6 \text{ V/m}$ at $T = 300 \text{ K}$.¹⁰ Thus no change of the ferroelectric domain structure is expected below room temperature.

Figure 4 shows how different states can be achieved via different heat treatments: The temperature is uniformly increased from below T_N up to a certain temperature T_a above T_N and then decreased again below T_N . The final domain state solely depends on T_a . Samples can be transformed into small- (path 1), medium- (path 3), or large-domain states (path 5) for values of temperatures $T_a > 250 \text{ K}$ (region D), $210 \text{ K} < T_a < 250 \text{ K}$ (region C), and $T_N < T_a < 210 \text{ K}$ (region B), respectively. Cooling or warming within region A does not change the domains (paths 2, 4, 6).

This is the first observation of such behavior of AFM domains. The most surprising result is that the average size of domains is sensitive to the annealing temperature T_a (larger than T_N) in the sense that the smaller the domains the higher T_a has been. The case of YMnO_3 thus contrasts with all previous observations, and the mechanism behind the observed behavior of domains remains rather unclear. Since the domain structure does not change at all below T_N , pinning effects are without any doubt strong and have to be taken

into account. Furthermore, the average domain size is influenced by various competing contributions to the free energy of the sample describing the formation of domain walls. Exchange and anisotropy energy, entropy and the bending of walls may be mentioned.^{5,6}

In conclusion, by use of nonlinear optical spectroscopy and a novel imaging technique for AFM domains, we have observed an unusual behavior of 180° domains in the easy-plane triangular antiferromagnet YMnO_3 . Depending on the annealing temperature $T_a > T_N$, the sample can be transformed into different states below T_N which are characterized by domains of small, medium, or large average size. The small-domain state with a large density of AFM domain walls is formed in crystals annealed at a sufficiently high temperature. This result contrasts with all previous observations of domains in antiferromagnets.

The wide applicability of nonlinear optical domain topography should stimulate further experimental studies, which should help to develop a plausible model for the observed static and dynamic properties of AFM domains and domain walls.

We have investigated the high frequency properties of several amorphous and polycrystalline wires mounted as inner conductors in coaxial lines. A static magnetic field was applied along the wire axis. The impedance spectra of the wires, measured using a network analyzer, show peaks in the real part of the impedance, which shift to higher frequency with the strength of the static field, a behavior typical of ferromagnetic resonance. The theoretical resonance condition predicts a straight line on an $f_0^2 - H_0$ plot, where f_0 is the resonance frequency and H_0 is the resonant field, whose slope depends only on the saturation magnetization, M_s , of the material. All our wires obey this relation, and the values of M_s calculated from the slopes are in good agreement with those measured directly using a vibrating sample magnetometer. © 1998 American Institute of Physics.

I. INTRODUCTION: GIANT MAGNETOIMPEDANCE AT SATURATION

The giant magnetoimpedance (GMI) at saturation is a magnetotransport effect recently observed in soft magnetic wires driven by ac current. It consists of a large change in the voltage drop across a wire subject to an axial dc magnetic field. As the voltage drop is proportional to the wire impedance when the current amplitude is fixed, the relative change in impedance, $\Delta Z/Z$, which occurs is:

$$\frac{\Delta Z}{Z} = \frac{|Z(H)| - |Z(H_{\text{ref}})|}{|Z(H_{\text{ref}})|},$$

where H is the axial magnetic field, $H_{\text{ref}}=0$, and $Z(H, \omega) = \text{Re } Z + j \text{Im } Z$. The GMI effect relies on phenomena known for many years: the skin effect and ferromagnetic resonance. GMI became noticed only after recent advances in materials technology resulted in the fabrication of ultrathin ferromagnetic wires.

The oscillating magnetic field created by the drive current in the wire is circumferential, as is the magnetic field in a transverse electromagnetic (TEM) propagating mode coaxial line. These fields are present in the wire only in a thin outer shell. A circumferential permeability, μ_ϕ , can be as-

sociated with these fields and the circumferential magnetization of the wire.

In the case of a permalloy wire at low to moderate frequencies (0.1–100 MHz), the GMI effect is negative and shows a significant decrease of the wire impedance when a saturating (200 Oe) magnetic field is applied. This phenomenon was explained by the influence of the technical saturation on the skin effect.^{1,2} In fact, the effective skin depth $\delta = \sqrt{2/\omega \mu_\phi \sigma}$ increases when the circumferential permeability

FIG. 1. Skin-effect in the TS and FMR regimes of GMI for a HyMu80 wire, plotted using an oscilloscope and microwave techniques, respectively.

^{a)}Electronic mail: ciureanu@lisa.polymtl.ca

FIG. 2. GMI responses of a HyMu80 wire determined using the technique described in Sec. II.

decreases upon the application of a longitudinal magnetic field. The real part of the wire impedance thus decreases, producing a 60% decrease of the voltage drop across the wire.

At high frequencies (1–10 GHz), the GMI effect is positive and shows a significant increase of the wire impedance when a saturating (200 Oe) magnetic field is applied. This phenomenon was explained by the ferromagnetic resonance occurring in the wire.³ The large circumferential permeability at resonance strongly decreases the effective skin depth and increases the impedance of the wire by up to 200%. Technical saturation (TS) dominates the skin effect in the radio frequency range (region I in Fig. 1), whereas ferromagnetic resonance (FMR) dominates the skin effect in the microwave range (region II).

The GMI effect has a very strong potential for sensing purposes. As shown in Fig. 2, the sensitivity of the permalloy wire depends on frequency, ranging between 1%/Oe at 10 MHz and 3.25%/Oe at 2 GHz. The purpose of this article is to show that, apart from sensing devices, the GMI effect can be useful for determining the intrinsic properties of magnetic materials.

FIG. 3. Impedance spectra of a HyMu80 wire.

FIG. 4. Magnetic field configurations in a thin planar film and in the thin outer shell of a cylindrical conductor.

II. EXPERIMENTAL DETAILS

Impedance spectra of soft magnetic wires were measured in the 10 MHz–6 GHz frequency range using a shorted coaxial line in the presence of a longitudinal magnetic field. The inner conductor of the line was replaced, in turn, by three different types of magnetic wire: polycrystalline HyMu80 permalloy ($\text{Ni}_{80}\text{Fe}_{16}\text{Mo}_4$) wires, amorphous NiCo-rich ($\text{Ni}_{45}\text{Co}_{25}\text{Fe}_6\text{Si}_9\text{B}_{13}\text{Mn}_2$) wires and amorphous CoFe-rich ($\text{Co}_{71}\text{Fe}_4\text{Si}_{14.5}\text{B}_{6.5}\text{Nb}_4$ and $\text{Co}_{68.2}\text{Fe}_{4.3}\text{Si}_{12.5}\text{B}_{15}$ -Unitika) wires. The HyMu80 wires were 44 or 118 μm in diameter and were cold drawn. The amorphous wires were 30 and 125 μm in diameter and were cast by rapid solidification. The length, l , of the wires was less than 1 cm. The input impedance per unit length of the coaxial line was measured using a network analyzer. The condition $l < \lambda/4$, where λ is the wavelength of the signal generated by the analyzer, is satisfied over the entire measurement range, so this impedance is close to that of the magnetic wire. Details of the experimental technique are given in Ref. 4.

The variation with frequency of the real part of the impedance of a permalloy wire, $\text{Re } Z$, for several static field strengths is shown in Fig. 3. $\text{Re } Z$, which is related to the magnetic losses, peaks at higher frequency for higher fields. The imaginary part of the impedance, $\text{Im } Z$, crosses zero at the same frequency where the maximum of the real part occurs, a behavior typical for ferromagnetic resonance. A resonance frequency, f_0 , can be determined for each value of the static field, H_0 .

FIG. 5. The square of the resonance frequency vs the resonance field for several soft magnetic wires. A linear fit of the experimental data was made in all cases (only data for $H_0 \geq 160$ Oe have been used in the case of the HyMu80 wire).

TABLE I. Saturation magnetization of several magnetic wires.

Wire alloy	Diameter (μm)	Length (mm)	R_{dc} (Ω)	ρ ($\mu\Omega\text{ cm}$)	M_s (10^6 A/m) GMI	M_s (10^6 A/m) VSM
(NiCo) ₇₀	33	2.76	3.2	100	0.250	0.27
(CoFe) ₇₅	28	6.5	17.2	160	0.628	0.68
HyMu80	44	7	2.1	46	0.691	0.71
CoFeSiB	125	5.5	0.7	156	0.644	0.64

III. FERROMAGNETIC RESONANCE

Ferromagnetic resonance occurs in samples submitted simultaneously to a longitudinal static field, which causes saturation of the sample and precession of the spins, and a perpendicular oscillating field, which provides the energy to maintain the precession and produces the resonance. In the presence of these fields, the dynamic equation of the magnetization of a ferromagnetic material (where damping has been neglected) is:⁵

$$\frac{d\mathbf{M}}{dt} = \gamma \mathbf{M} \times \mathbf{B} = \gamma \mu_0 \mathbf{M} \times \mathbf{H}, \quad (1)$$

where

$$\mathbf{H} = \mathbf{H}_0 + \mathbf{H}(t) \quad \text{and} \quad \mathbf{M} = \mathbf{M}_s + \mathbf{M}(t). \quad (2)$$

In Eq. (2), \mathbf{H}_0 is a large static field applied parallel to the z axis, whereas $\mathbf{H}(t) = H e^{j\omega t}$ is a small oscillating field perpendicular to the static one. \mathbf{M}_s is the saturation magnetization aligned in the static field direction, whereas $\mathbf{M}(t) = M e^{j\omega t}$ adds a small oscillating component normal to \mathbf{M}_s . The resonance frequency for a thin ferromagnetic film containing the z axis in its plane [Fig. 4(a)] can thus be written as⁶

$$\omega_0 = \gamma \mu_0 \sqrt{\mathbf{H}_0(\mathbf{H}_0 + \mathbf{M}_s)}, \quad (3)$$

where $\gamma = 0.176 \times 10^{12} (\text{Ts})^{-1}$ is the gyromagnetic ratio of the electron. When $H_0 \ll M_s$, which applies well for all the wires, Eq. (3) simplifies to

$$\omega_0 \approx \gamma \mu_0 \sqrt{\mathbf{H}_0 \mathbf{M}_s}. \quad (4)$$

The field geometry for the giant magnetoimpedance effect in a magnetic wire driven by a rf current or used as a central conductor in a coaxial line in which a microwave signal is propagating [Fig. 4(b)] may be mapped onto that of the ferromagnetic resonance in a thin magnetic film submitted to fields \mathbf{H}_0 and $\mathbf{H}(t)$. For the wire, the oscillating field $\mathbf{H}(t)$ created by the oscillating current $\mathbf{I}(t)$ is circumferential, as is the magnetic field in a TEM propagating mode coaxial line. Due to the skin effect, these fields are present only in a thin outer shell of the wire. By unrolling the outer shell into a plane, we obtain the same field configuration as for a planar film: the oscillating field is perpendicular to the static field. Thus, when the skin depth is small compared to the wire radius (for example, permalloy wires 44 μm in diameter have a skin depth of 0.22 μm at 4.5 GHz), Eq. (4) applies also to the wires,⁷ and can be written in SI units as

$$f_0^2 = \left(\frac{\gamma \mu_0}{2\pi} \right)^2 M_s H_0 \approx 1.24 \times 10^9 M_s H_0. \quad (5)$$

Equation (5) predicts a straight line with zero intercept for a plot of f_0^2 vs H_0 , whose slope is determined by the

saturation magnetization of the material. Figure 5 indicates that data for all three materials obey such a linear relation and, in all cases, the straight lines pass through the origin. The saturation magnetization can be calculated as

$$M_s = 0.805 \times 10^{-9} \frac{df_0^2}{dH_0} (\text{A/m}), \quad (6)$$

where f_0^2 is expressed in $(\text{GHz})^2$ and H_0 in A/m.

IV. DISCUSSION

Using the values of the slopes calculated from Fig. 5 in Eq. (6), the saturation magnetizations of NiCo-rich, CoFe-rich, and permalloy wires were determined and compared in Table I with the results obtained using a vibrating sample magnetometer (VSM). A good agreement was found for the M_s values obtained through the two methods.

In calculating the slope of the $f_0^2 - H_0$ line for permalloy using only high field data, the contribution of the anisotropy field was neglected.

One source of possible differences between GMI and VSM measurements of M_s may be the inhomogeneity of M_s through the cross section of the magnetic wire. GMI-related phenomena take place only in a thin outer layer of the wire, where permeability inhomogeneity, oxidation and surface defects may occur, whereas VSM provides average values of M_s . Another possible source of disagreement is the error in determining the sample volume, necessary for the VSM.

Thus, we have demonstrated that the giant magnetoimpedance effect of magnetically soft wires at high frequencies is a result of skin depth variations produced by the ferromagnetic resonance occurring in the material. This approach permitted us to determine the saturation magnetization of different samples using GMI measurements, which offer accurate data over a much broader frequency range than ferromagnetic resonance measurements, for example.

Giant magnetoimpedance (GMI) at 10 MHz and longitudinal magnetization curves are used to investigate the anisotropy of $\text{Co}_{68.15}\text{Fe}_{4.35}\text{Si}_{12.5}\text{B}_{15}$ wires, glass-covered and after glass removal. The high resolution GMI response to the field shows hysteresis and large Barkhausen jumps, in good agreement with those observed in the magnetization curves. These are modeled through superposition of the response of the inner core and outer shell of the wires. The GMI response is calculated using the differential susceptibility deduced from the model, thus relating the domain structure to the observed magnetoimpedance. © 1998 American Institute of Physics. [S0021-8979(98)24111-9]

I. INTRODUCTION

The anisotropy in soft amorphous magnetic wires is due partly to exchange and magnetostatic effects, and partly to magnetoelastic effects. The latter are quite effective in amorphous glass-covered wires (AGCW), due to large residual stresses.¹ Removal of the glass, leading to significant stress relief, produces a major change in the magnetic structure of these wires.

Recent reports^{2,3} have discussed the effect of applied tensile and torsional stresses on the anisotropy of Co-rich and Fe-rich AGCW and wires after glass removal (WAGR). For instance, dynamic axial hysteresis loops were measured to investigate the remanence, the coercivity and the occurrence and disappearance of large Barkhausen jumps, from which possible domain structure was inferred.

Here, high resolution giant magnetoimpedance (GMI) and magnetometry are compared to investigate the magnetic structure of these wires. A quasistatic model due to Nowak⁴ is applied to interpret the results, yielding interesting insights into the magnetic structure and the GMI response of wires.

II. PHENOMENOLOGICAL MODELING

The model is based on a core-shell domain structure consisting of a cylindrical inner core (IC) with an axial easy axis, surrounded by an outer shell (OS) with a circumferential easy axis. The quasistatic magnetic hysteresis of each part of the wire is described using a modification, proposed by Nowak,⁴ of the Stoner-Wolfarth model for thin ferromagnetic films with in-plane anisotropy. The model is adapted to the cylindrical geometry by considering that the circumferential direction of the wires is equivalent to the transverse direction of the films.

The global magnetization of the wire is the sum of the magnetizations of the IC and the OS

$$M = \alpha M_{\text{IC}} + (1 - \alpha) M_{\text{OS}}, \quad (1)$$

where α is the relative volume of the IC. The axial magnetization of the IC and the OS region as a function of the longitudinal applied field H are given by⁴

$$M_i(H) = M_s \cos[\varphi_i(H)], \quad (2)$$

where

$$\varphi_i(H) = \tan^{-1} \left(\frac{T_i}{H + L_i} \right) + p\pi \quad (3)$$

is the equilibrium angle between the local magnetization and the applied axial field. In Eq. (2), M_s is the saturation magnetization and p (equal to either 0 or 1) is required to select the appropriate argument of the cosine function. The parameters L_i and T_i are the longitudinal and transverse components of an effective internal field with respect to the direction of the applied field for the two regions. The longitudinal field L_i gives the width of the loop, while the transverse field T_i is responsible for the squareness and the slope of this loop.

It is useful to establish a link between the magnetization curves and the giant magnetoimpedance, which is currently explained by the significant variation of the skin depth due to the sensitive dependence of the circumferential permeability μ_φ upon the application of the longitudinal field.⁵

The impedance of a magnetic wire⁵

$$Z = R_{\text{dc}} \frac{ka J_0(ka)}{2 J_1(ka)}, \quad \text{with} \quad k = \frac{1-i}{\delta}, \quad (4)$$

is a function of the effective skin depth, $\delta = \sqrt{c^2/2\pi\omega\sigma\mu_\varphi}$, where c is the velocity of light, σ the electrical conductivity, ω the angular frequency of the drive current, R_{dc} the dc re-

^{a)}Electronic mail: menard@lisa.polymtl.ca

sistance, $J_0(ka)$ and $J_1(ka)$ are Bessel functions and a is the radius of the wire. Obviously, any attempt to model the GMI requires an expression for the circumferential permeability

$$\mu_\phi = \frac{\partial B_\phi}{\partial H_\phi} = 1 + 4\pi \frac{\partial M_\phi}{\partial H_\phi}. \quad (5)$$

In the present context, M_ϕ is the circumferential magnetization with a form similar to Eq. (2), with $\cos(\varphi_i)$ replaced by $\sin(\varphi_i)$. The differential susceptibility, for a given region of the wire, is then calculated by adding the small circumferential driving field h_ϕ to T_i in the numerator of Eq. (3), and taking the derivative of M_ϕ with respect to h_ϕ . This results in

$$\mu_\phi = 1 + 4\pi M_s \frac{H + L_i}{(H + L_i)^2 + T_i^2} \cos[\varphi_i(H)] \quad (6)$$

from which we obtain the skin depth, and therefore the GMI response to the applied field.

III. EXPERIMENTAL METHOD

GMI and longitudinal magnetization curves were measured in nearly-zero magnetostrictive $\text{Co}_{68.15}\text{Fe}_{4.35}\text{Si}_{12.5}\text{B}_{15}$ glass-covered wires and in the same wires after glass removal. The 20 mm-long metallic samples, with a nominal diameter of $27 \mu\text{m}$ ($R_{dc} \approx 50 \Omega$) were initially covered by a glass sheet about $6 \mu\text{m}$ thick. The chemical glass removal process is described in Ref. 1.

The longitudinal magnetization curves were obtained in the -10 – $+10$ Oe range with a vibrating sample magnetometer (VSM) operating in high resolution field regime. The GMI was measured at 10 MHz using a HP4192A impedance analyzer. The drive current was kept below 0.6 mA, producing a maximum rf field of 0.03 Oe at the surface of the samples. The longitudinal static magnetic field was produced with a pair of Helmholtz coils connected to a programmable current source and controlled by a computer. Automatic data acquisition was performed in cycles ranging between -4 and $+4$ Oe with a resolution of 0.01 Oe.

IV. RESULTS AND DISCUSSION

Hysteresis curves for the AGCW and WAGR are shown in Figs. 1(a) and 1(b), respectively, along with calculations based upon Eq. (1). A small correction due to the demagnetizing field has been applied to the external field. Figure 1(a) clearly shows the presence of two distinct mechanisms. The large Barkhausen jump (LBJ) observed for $H \approx \pm H_c = 0.1$ Oe, gives evidence for a domain structure with axial easy axis, while the external part of the curve ($|H| > H_c$) is dominated by rotational mechanisms relating to the transverse anisotropy. The WAGR sample [Fig. 1(b)] has a lower $H_c = 0.05$ Oe and a larger LBJ.

The intrinsic material parameters extracted from these curves are summarized in Table I. The saturation magnetization M_s , is defined here as the magnetization for a 10 Oe applied field. The difference between the M_s value for the two types of wire is primarily attributed to uncertainties in determination of the volume. The anisotropy fields, H_K ,

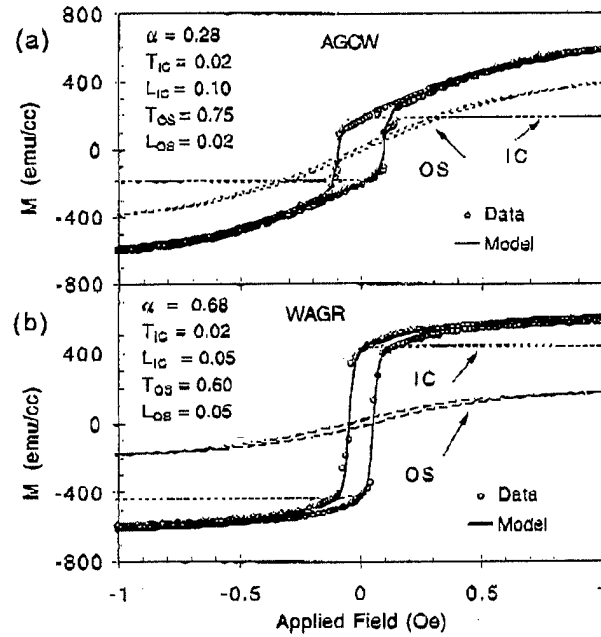

FIG. 1. Comparison between experimental data and a simple model for hysteresis loops in (a) AGCW and (b) WAGR.

were estimated from the slopes of the external part of the curves close to the origin $H=0$, and from first magnetization curves.

The agreement between the model and the experimental data in Fig. 1 is good. The parameters used for the fit are shown in the figure. The effective fields give an indication of the anisotropy in each region of the wire. The longitudinal field L_{IC} corresponds to the coercive field H_c of the IC region, while the transverse field T_{OS} reflects the anisotropy field H_K of the OS.

The factor α was estimated by the reduced remanent magnetization M_r/M_s which gives a direct estimation of the relative volume occupied by the axial domains, that is $M_r/M_s = r_{IC}^2/a^2$, where r_{IC} is the inner core radius. The data of Table I indicate that the removal of the stress provided by the glass cladding results in a significant expansion of the inner core from 53% to 83% of the wire radius. This behavior is due to stress relief, which results in the increased importance of the exchange and magnetostatic energies (facilitating axial magnetization) compared to the magnetoelastic term (facilitating circumferential magnetization).

The GMI responses for both wires, presented in Fig. 2(a) and Fig. 2(b), reflect the circumferential bias permeability ($Z \sim \mu_\phi^{1/2}$). The AGCW wire has a double-peaked response, typical of the permeability of a magnetic layer measured along the easy axis in the presence of a bias field along the hard axis, while the WAGR shows a single peak at the ori-

Sample	M_s (emu/cc)	M_r/M_s (%)	H_c (Oe)	H_K (Oe)
AGCW	675	28	0.10	0.8
WAGR	645	68	0.05	0.5

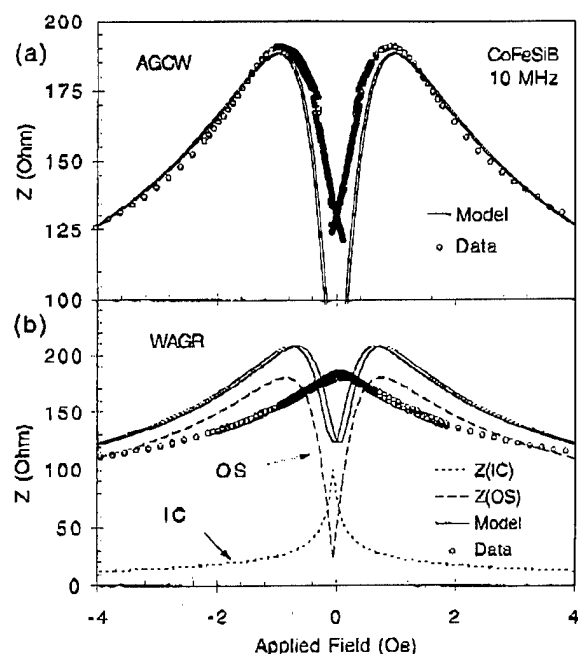

FIG. 2. Comparison between experimental data and a simple model of the modulus of the impedance as a function of the static field for (a) AGCW and (b) WAGR. The data were collected from -4 to $+4$ Oe and then back to -4 Oe.

gin, typical of the bias field parallel to the easy axis.⁴ For the field range under study, the effective skin depth calculated from Eq. (6), is found to vary between 15% and 30% of the wire's radius, so that the GMI response is dominated by the OS in both wires.

The modeling of the AGCW, in Fig. 2(a), based on the parameters of the OS calculated from the magnetization curves, shows good agreement with the experimental data, except at very low fields. This behavior suggests that the sample breaks up into a complicated domain structure in this range. However, using the parameters of the OS region for the WAGR [Fig. 2(b)], the model is unable to fit the experimental data. Including a contribution from both regions,

FIG. 3. Details of the low field behavior of the GMI response for the data shown in Fig. 2. The thin arrows show the direction of the sweeping field.

weighted by an appropriate factor, also fails to accurately describe the results, as shown in Fig. 3. Indeed, from the value of the skin depth at different fields and the relative volume occupied by the two regions, we find that 2% to 10% of the IC is within the skin depth. This may correspond to a transition region between the inner and outer regions, for which the domain structure remains unclear.

The detailed response of the GMI near the origin (Fig. 3) shows an asymmetric and hysteretic cycle in the low field range ($H < 0.5$ Oe) for the AGCW, characterized by discontinuities at the coercive points observed in the magnetization curves. Repeated measurements verify the reproducibility of the jumps. They appear consistently at the same field as it is swept back and forth, so that they must reflect reproducible features of the domain structure. Similar jumps were also observed in the WAGR sample.

It is somehow puzzling to observe LBJ, which were previously attributed to the IC, in the GMI response of the OS. However, this feature can be reasonably explained by introducing an additional effective field $\pm H_x$ in the OS due to an exchange coupling with the IC, whose sign depends upon the state of the IC. When the applied field reaches the critical field for which the magnetization of the IC reverses ($H \sim H_c$), the effective field in the OS jumps from $H - H_x$ to $H + H_x$, thus producing a discontinuity in the GMI response. The model for the AGCW is in qualitative agreement with this behavior as shown in Fig. 3.

The additional smaller jumps at ± 0.3 Oe for the AGCW shown by the broad arrows in Fig. 3 have no equivalent in the magnetization curves, reflecting the fact that the real domain structure is more complicated.

V. CONCLUSION

We have used a simple yet plausible model to describe the anisotropy of soft magnetic wires. The model gives a reasonable interpretation of the hysteresis loops and provides interesting insights into the GMI effect. In particular, the large Barkhausen jumps are correctly explained by the introduction of an exchange coupling between the inner core and the outer shell regions. In addition, the model yields an analytic expression for the GMI which works well in AGCW, but fails to describe the response in the WAGR. However, a more realistic approach based on a calculated quenched-in stress distribution is required to clearly establish the effect of the stress on the GMI response.

Phenomenological model for magnetoimpedance in soft ferromagnets

D. Atkinson and P. T. Squire^{a)}

Department of Physics, University of Bath, Bath BA2 7AY, United Kingdom

The dependence of magnetoimpedance (MI) on transverse susceptibility in soft ferromagnets is used in conjunction with an existing phenomenological domain structure model to study the relative importance of moment rotation and domain-wall motion in MI. It is shown that moment rotation is predominantly responsible for the observed behavior in amorphous wires at frequencies above 1 MHz. It is also necessary to include anisotropy distributions in both magnitude and direction.

© 1998 American Institute of Physics. [S0021-8979(98)39411-6]

INTRODUCTION

Very large magnetoimpedance (MI) is observed in soft ferromagnets at frequencies upwards of 10 kHz.¹ The origin of this behavior is recognized as magnetoinductance and skin-depth effects, and the link between the domain structure and anisotropy and the magnitude of the MI is also established.² However, efforts to model MI in terms of magnetization processes associated with a particular domain structure are limited.³ Notably, the relative importance of domain-wall motion and magnetization rotation processes and the effect of easy axis orientation have not been clearly addressed.

In this work, a phenomenological model relating the domain structure and magnetization processes of a ferromagnet to the transverse susceptibility and the MI response is presented.

PHENOMENOLOGICAL MODEL

The relationship between the impedance and the magnetic permeability of a conductor is understood through classical electromagnetism and described in terms of the skin-depth effect.⁴ The complex impedance of a cylindrical conductor can be described in the form

$$Z = R_{dc}kaJ_0(ka)/2J_1(ka), \quad (1)$$

where R_{dc} is the dc resistance of the wire, a its radius, J_0 and J_1 are Bessel functions of the first kind, and $k = (1+j)/\delta$, where δ is the skin depth. At higher frequencies ($|ka| \gg 1$), the asymptotic form of the Bessel functions allows the impedance to be expressed as

$$Z = R + jX, \quad (2)$$

where

$$R \approx X \approx R_{dc} \left(\frac{a}{2\delta_0} \right) \sqrt{\mu_r}, \quad (3)$$

δ_0 is the skin depth when the relative permeability $\mu_r = 1$, and is given by

$$\delta_0 = \sqrt{\frac{2\rho}{\mu_0\omega}}, \quad (4)$$

where ρ is the resistivity and ω is the angular frequency.

For a ferromagnetic material, the magnetic-field dependence of the permeability, therefore, controls the MI behavior of the conductor.

It follows that magnetoimpedance can be understood by expressing the permeability along an appropriate axis as a function of the magnetic field. For cylindrical (wire) geometry the appropriate permeability is circumferential and for planar geometry (ribbons and thin films) it is transverse, with respect to the axis of current flow. The permeability depends on many factors, including the domain configuration, anisotropy, stress, and the mode of magnetization (domain-wall motion or magnetization rotation). These factors can be complex in real materials, making accurate modeling very difficult.

This work is based on the model of Squire⁵ for magnetization and magnetoelastic effects in soft ferromagnets. The model assumes a simplified domain structure, consisting of antiparallel domains separated by 180° domain walls; a single, arbitrary easy axis orientation; and magnetization processes which are anhysteretic. Both domain-wall motion and magnetization rotation are included in the model, allowing their relative contributions to the transverse permeability to be investigated. Figure 1 schematically illustrates the domain structure and angles used in the model. The model excludes domain-wall bowing and rotational damping.

The model is applicable to both cylindrical and planar geometries, which differ only in terms of the magnitude of the transverse demagnetizing energy. For cylindrical geometry, the circumferential demagnetizing field is very small

FIG. 1. Geometry assumed for the domain model. The easy axis makes an angle θ with the dc field axis. Moments in the two types of domains make angles of ϕ_1 and ϕ_2 with the easy axis under the combined influence of the axial field H^{ax} and the transverse field H^t . The domain widths are both taken as d in zero applied field; x denotes the field-induced domain-wall movement.

^{a)}Electronic mail: p.t.squire@bath.ac.uk

since the circumferential magnetization is essentially continuous. In the case of a planar geometry, the transverse demagnetizing field depends on the width of the sample.

The model is used to calculate the transverse susceptibility χ^t , which is simply related to the relative permeability ($\mu_r = \chi^t + 1$). The transverse susceptibility is derived from the magnitude of the transverse magnetization developed by the magnetic field due to the current in the material.

Modeling involves minimization of the free-energy density to determine the domain structure (domain-wall positions and magnetization rotation angles) obtained when the material is subject to both transverse and axial magnetic fields. The free-energy density includes the following terms:

$$U_{\text{tot}} = U_K + U_H^{\text{ax}} + U_H^t + U_W, \quad (5)$$

where U_K is the uniaxial anisotropy energy density, taken as

$$U_K = K[\alpha \sin^2 \phi_1 + (1 - \alpha) \sin^2 \phi_2], \quad (6a)$$

where K is the anisotropy constant. The parameter α is the fraction of material occupied by domains magnetized towards the applied axial field (Fig. 1). U_H^{ax} is the Zeeman energy due to the axial magnetic field H^{ax} :

$$U_H^{\text{ax}} = \mu_o M_s H^{\text{ax}}[(1 - \alpha) \cos(\theta + \phi_2) - \alpha \cos(\theta - \phi_1)], \quad (6b)$$

U_H^t is the Zeeman energy due to the transverse magnetic field, H^t :

$$U_H^t = \mu_o M_s H^t[(1 - \alpha) \sin(\theta + \phi_2) - \alpha \sin(\theta - \phi_1)], \quad (6c)$$

and U_W is the magnetostatic energy, which depends on the domain-wall position. A parabolic potential is used to represent this contribution:

$$U_W = \beta u^2, \quad (6d)$$

where $u = x/d$ and β is a measure of the domain-wall stiffness.⁵ The procedure is to choose the values of moment angle ϕ_1 , ϕ_2 , and domain-wall position α that minimize U_{tot} in a given axial field H^{ax} with the transverse field H^t equal to zero; then, to find the changes in these parameters induced by a small transverse field. The difference ΔM between the transverse magnetization with and without a transverse field allows the transverse susceptibility $\chi^t = \Delta M/H^t$ to be calculated.

Here, the model is addressed to three aspects of the relationship between magnetoimpedance and the domain structure. (Previous results concerning the effect of applied stress on MI have been reported elsewhere⁶). The first aspect addressed is the relationship between the magnetization processes and the MI effect. It is clear from many observations of magnetoimpedance that the shape of the MI (H) curve is a function of the frequency of the excitation current. It is also established from permeability studies that domain-wall motion becomes increasingly heavily damped due to eddy currents at high frequencies.⁷ The model has, therefore, been applied to calculate the transverse susceptibility for a material in which the amount of domain-wall motion due to the transverse field was made progressively smaller.

FIG. 2. Transverse susceptibility calculated for $\theta=90^\circ$ as a function of the applied-field H , normalized to the anisotropy-field H_a . The parameter β controls domain-wall movement: large values of β inhibit wall motion [see Eq. 6(d)].

The second aspect studied here is the relationship between the anisotropy easy-axis orientation θ and the MI response. Observations have shown that the shape of the MI (H) curves depends on the easy axis orientation. Finally, the effects of a distribution in anisotropy magnitude on the MI response of materials has been studied.

RESULTS AND DISCUSSION

Figure 2 shows the effect of increasingly restricted wall motion on the transverse susceptibility of a material with a perpendicular ($\theta=90^\circ$) anisotropy. For small β values [Eq. 6(d)], domain walls move easily under the influence of the transverse field. In this case, the transverse susceptibility falls as the axial field increases because the transverse magnetization in each domain is reduced as the moments rotate towards the axial field. This behavior is to be expected at relatively low frequencies where eddy-current damping of domain-wall motion is negligible. For intermediate values of β , the relative contribution of domain-wall motion to the transverse susceptibility decreases. For high values of β , domain-wall motion is negligible and the transverse susceptibility is due only to magnetic-moment rotation. In this case, the transverse susceptibility is zero when the axial field is zero and increases with axial field until close to the anisotropy field. The transverse susceptibility then falls with a further increase of the axial field. This behavior is expected at higher frequencies, when eddy currents severely damp domain-wall motion. This indicates, therefore, that for MI of amorphous wires and transverse-field annealed ribbons observed at ≥ 1 MHz magnetic-moment rotation is the dominant mechanism responsible for the magnetoimpedance. Figure 2 also shows that above the anisotropy field the three curves converge. This occurs because for axial fields greater than the anisotropy field the moments are aligned with the axis; the transverse susceptibility is due only to a small perturbation of the moments from this axis.

Figure 3 illustrates the influence of the anisotropy easy-axis angle θ on the transverse susceptibility due to magnetization rotation (appropriate to high frequencies). The shape of the transverse susceptibility curve evolves from the high

FIG. 3. Effect of different easy-axis orientations on the transverse susceptibility.

angle case, in which the susceptibility rises from a low value to a peak and then falls with further increase of the axial field, to the lower angle case in which the transverse susceptibility falls monotonically with the axial magnetic field. This result is again consistent with experimental MI observed in as-quenched and annealed amorphous ribbons and wires.^{2,6}

It is known from modeling of magnetic and magnetoelastic effects that some level of distribution in the anisotropy magnitude and easy-axis orientation is required to rep-

FIG. 4. Comparison of the experimental field dependence of the resistive component of magnetoimpedance with the model. Optimum fit is obtained by assuming a Gaussian distribution of anisotropy magnitude with 3σ limits equal to 20% of the mean.

resent the behavior of amorphous alloys.⁵ Figure 4 shows the resistive component of the impedance for an as-quenched $\text{Co}_{72.5}\text{Si}_{12.5}\text{B}_{15}$ amorphous wire, subject to axial, tensile stress of 170 MPa, and a modeled curve which assumes rotational magnetization processes, an easy-axis orientation of $\theta=90^\circ$, and a Gaussian distribution of the anisotropy constant. There is good agreement between the data and the model except at low fields, supporting the presence of an anisotropy distribution in the wire. The anisotropy distribution can be attributed to variations of the internal stress in the wire. The discrepancy between the model and the data at low fields most probably arises from a distribution of the easy-axis orientation around the assumed value of 90° .

CONCLUSIONS

A static, phenomenological model, developed originally for the calculation of magnetic and magnetoelastic properties, has been effectively extended to calculate the transverse susceptibility, and hence, magnetoimpedance in soft ferromagnets. The model includes domain-wall motion and magnetic-moment rotation, but excludes domain-wall bowing and rotational damping.

Modeling shows that the basic shape of the MI as a function of applied field is governed by the easy-axis orientation and the magnetization processes contributing to the transverse susceptibility. Comparison of the model with published experimental data indicates that at frequencies of about 1 MHz and above magnetization rotation is largely responsible for the MI response in CoFeSiB wires and ribbons. The model also suggests that the MI response of amorphous alloys reflects a distribution of the magnitude of the anisotropy.

Field and stress dependence of the irreversible magnetization changes in pure iron

J. Pearson and P. T. Squire^{a)}

Department of Physics, University of Bath, Bath, BA2 7AY, United Kingdom

Measurements of the irreversible magnetization changes accompanying the application and removal of stress to a sample of 99.99% pure iron have been made as a function of applied field and stress magnitude for both compressive and tensile stress. The fields for peak change have been compared with those for the peak difference $M_{AN} - M_{INI}$ between the anhysteretic and initial magnetization curves and the field derivative of the magnetostriction. It is shown that at low tensile stress the magnetostrictive contribution is dominant, as found by Pravdin. At higher stress the wall pinning term is dominant, and the magnetization changes are proportional to $M_{AN} - M_{INI}$, in accordance with the Jiles–Atherton model. © 1998 American Institute of Physics. [S0021-8979(98)24211-3]

I. INTRODUCTION

There have been numerous studies exploring the effects of stress on the magnetic properties of ferromagnetic materials. A good review has been given by Robertson.¹ Despite the extensive study there has never been an adequate explanation of the complicated history-dependent effects that have been observed. Early work by Brown² suggested that, on the initial magnetization curve, stress should act as an additional pressure on a domain wall. This pressure varies for different domain wall types, but gives equal magnetization changes in tension and compression. This approach had some success for field and stress changes within the Rayleigh region, but not beyond. Later work by Birss,³ Faunce and Isaac,⁴ and Craik and Wood⁵ showed that the experimental results could only be explained if stress affected the magnetization in three ways:

- altered the pinning site energies;
- induced preferential occupancy of a particular axis, encouraging domain creation and or annihilation;
- produced direct pressure on non-180° domain walls.

Jiles and Atherton⁶ (JA) have developed a theory based on domain wall motion. In the JA model the change in magnetization induced by the application and release of an applied stress (ΔM_{IRR}) was proportional to the difference between the initial (M_{INI}) and anhysteretic magnetization curves (M_{AN}). It proposes that an applied stress acted to help a domain wall overcome its local pinning sites, allowing a domain wall to move towards its thermal equilibrium position, which is assumed to be the anhysteretic. Figure 12 in Ref. 6 compares the difference $M_{AN} - M_{INI}$ with ΔM_{IRR} as a function of applied field for a stress of 140 MPa. Although there are qualitative similarities, the peak change in ΔM_{IRR} clearly occurs at a higher field value than the difference $M_{AN} - M_{INI}$. Pravdin^{7,8} looked at the effect of low-magnitude cyclic stress, separating the irreversible and reversible changes after many cycles. Although not mentioned in his work, it is clear from Fig. 5 in Ref. 7 that ΔM_{IRR} in tension peaked at a higher field value than ΔM_{IRR} in com-

pression. Pravdin showed that these changes were not proportional to χ or $M_{AN} - M_{INI}$ (Jiles–Atherton) but corresponded to the differential magnetostriction ($\partial\lambda/\partial H$).

The present study extends the work of Pravdin to higher magnitude stresses. We will show how the peak position of ΔM_{IRR} varies with the magnitude and sign of the applied stress and explore the possible reasons for this variation.

II. EXPERIMENTAL DETAILS

Experiments were carried out on a 2 mm diameter, 150 mm long piece of 99.99% pure iron rod. Magnetization of the sample was measured using the ballistic method with software integration of the induced voltage. The magnetic field was provided by a solenoid. The stress was applied using an electromagnetic actuator and a lever system for mechanical advantage. The rate of application of stress was maintained constant throughout the experiment. Demagnetization of the sample was by the alternating field method with a 1% reduction in the peak field value per cycle. Comparison with a 0.1% reduction per cycle showed a negligible difference in the data. A typical measurement occurred as follows. The sample was demagnetized under zero stress. A known bias field was applied. The required stress was applied and released in several steps, measuring the induced search coil voltage at each step. The whole process was repeated for bias fields ranging from 0 to 6000 A/m with the same applied peak stress. The anhysteretic data were produced by demagnetizing the sample in a dc bias field, then saturating the sample and measuring ΔM . Experimental uncertainty was estimated from three measurements at each data point. Variations in the applied stress introduced most of the uncertainty in the data. For example, applying 9.5 MPa instead of 10 MPa could introduce a 5% difference in consecutive measurements. The error bars are therefore proportionally larger as the applied stress decreases. Errors in software integration drift have been minimized to less than 0.01 mT per point and are therefore negligible in these measurements.

FIG. 1. Irreversible magnetization change as a function of the applied field after application and release of 47 MPa tension.

Magnetostriction was measured as a function of applied field by means of a fiber-optic dilatometer.⁹ The quantity $(\partial\lambda/\partial H)$ was derived in software from the experimental $\lambda(H)$ data.

III. RESULTS AND DISCUSSION

Figure 1 shows ΔM_{IRR} as a function of applied field due to the application and release of 47 MPa tension. This is typical of the data sets at various peak stresses, from which the peak positions and magnitudes were derived by curve fitting. Figure 2 shows how $(\partial\lambda/\partial H)$ varies with applied field. Curve fitting shows that this peaks at 2035 ± 35 A/m. Figure 3 shows how the peak position of ΔM_{IRR} varies with absolute applied stress. The extrapolated value at $\sigma=0$ is 1720 ± 240 A/m. Figure 4 shows how $\Delta M_{\text{IRR}}(\text{max})$ varies as a function of applied stress. Values have been calculated from curve fitting parameters obtained from data sets like Fig. 1. Figure 5 shows the difference $M_{\text{AN}} - M_{\text{INI}}$ as a function of applied field. Figure 6 shows how the peak position of $M_{\text{AN}} - M_{\text{INI}}$ varies with absolute applied stress.

On average, no moment direction is preferred in the demagnetized state and hence stress has no macroscopic effect on the magnetization. Increasing the field from the demag-

FIG. 2. Magnetostriction and its field derivative.

FIG. 3. Variation of the peak position of irreversible magnetization as a function of magnitude of peak stress. The error bars are obtained from curve fitting parameters.

netized state induces a preferred direction and hence the application of a *small tensile* stress changes the magnetization by the methods outlined in the introduction.

We write

$$P_{\sigma} \propto \frac{\partial \lambda}{\partial H},$$

$$P_H \propto \mu_0 H M_S,$$

and

$$P_{\text{PIN}} \propto \frac{\partial E_{\text{PIN}}}{\partial x},$$

for the pressures on the domain wall due to the applied stress and field respectively. P_{PIN} is the restoring pressure due to the wall pressure energy density gradient. In simple terms a pinned domain wall will “jump” from its pinning site when

$$P_H + P_{\sigma} > P_{\text{PIN}}.$$

If some of the pinning sites are magnetostrictive and of both tensile and compressive types,¹⁰ then tensile stress raises and lowers an equal number of pinning site energies. In a planar wall system consider the effect of P_{PIN} only. If tensile stress has the effect of increasing P_{PIN} at a pinned domain wall, then to compensate there will be a small, usually reversible,

FIG. 4. Peak magnetization change as a function of applied stress. Error bars are obtained from curve fitting parameters.

FIG. 5. Difference between the anhysteretic and initial magnetization curves, $M_{AN} - M_{INI}$, as a function of applied field at zero stress.

decrease in magnetization. However, if the restoring pressure, P_{PIN} decreases, then the magnetization will increase, and a fraction of the pinned domain walls will irreversibly jump to the next local energy minimum. The irreversible increases will be larger than the reversible decreases in magnetization. In this way, on average, ΔM_{IRR} due to changes in P_{PIN} should always increase the magnetization towards the anhysteretic value. This change will be at a maximum when most domain walls are pinned, that is at the peak in $M_{AN} - M_{INI}$. However, this does not consider the P_σ term which, to first order, only affects non-180° domain walls. Therefore, at low tensile stress, the peak in ΔM_{IRR} due to changes in P_σ and P_{PIN} occurs at a higher field value than the peak in $M_{AN} - M_{INI}$, closer to the peak in $(\partial\lambda/\partial H)$ shown in Fig. 2. As the stress value increases, the change in P_{PIN} begins to dominate the changes in ΔM_{IRR} and hence we see a shift in the peak position of ΔM_{IRR} towards the peak in $M_{AN} - M_{INI}$ as seen in Fig. 2. In compression the situation is more complicated, in that the change in P_{PIN} increases, while the change in P_σ decreases the magnetization. For this iron sample the net result is an increase in magnetization but very little change in the peak position of ΔM_{IRR} with applied field.

Figure 4 gives an indication of why accurate measurement of the peak positions are difficult at low stress due to the low induction change. Hence on this sample it is impossible to say whether the peak in ΔM_{IRR} coincides exactly with the peak in $(\partial\lambda/\partial H)$ as $\sigma \rightarrow 0$, or only that it approaches it. These trends cannot be attributed to changes in M_{AN} under stress as would be the case in the JA model. Figure 6 shows that the positions of the peak in $M_{AN} - M_{INI}$, as seen in Fig. 3, diverge as the applied stress increases.

FIG. 6. Variation of the peak position of $M_{AN} - M_{INI}$ as a function of absolute applied stress.

IV. CONCLUSIONS

We have shown that the peak position of ΔM_{IRR} cannot be explained by the JA model at low stress. At low tensile stress the peak in ΔM_{IRR} is closer to the peak in $(\partial\lambda/\partial H)$, as suggested by Pravdin. As the magnitude of the applied stress increases, the peak in ΔM_{IRR} moves towards the peak in $M_{AN} - M_{INI}$, as predicted in the JA model. We have shown that this change is due to stress affecting the magnetization by different mechanisms at different stress magnitudes. At low stress the primary change is due to P_σ which is proportional to $(\partial\lambda/\partial H)$. As the stress increases, changes in P_{PIN} begin to dominate, which are proportional to $M_{AN} - M_{INI}$.

In further work we hope to establish that these trends are true for other materials. (Such as Ni, SiFe, and steel.)

The temperature dependence of the magnetoimpedance (MI) effect is important both for scientific study and for thermal stability of MI sensors. We have performed the measurement of MI effect in amorphous $\text{Co}_{66}\text{Fe}_4\text{NiB}_{14}\text{Si}_{15}$ (Metglas 2714A) ribbon from a cryogenic chamber where the temperature of the sample can vary from 10 to 300 K. The ac current was fixed at 10 mA for all measured frequencies ranging from 100 kHz to 10 MHz. The magnetoimpedance ratio (MIR) was revealed the drastic increment as a function of $\text{MIR}(T) = \text{MIR}(0)\exp(cT^2)$, where c is a constant. The measured MIR values at room temperature are usually 2–3 times larger than the data measured at 10 K for all measured frequencies. However, the shapes of the MIR curves are remained. This result shows the potential application of the MI effect for a temperature sensor. © 1998 American Institute of Physics. [S0021-8979(98)24311-8]

I. INTRODUCTION

Recently, large and sensitive changes in the alternating current magneoresistance, called as magnetoimpedance (MI) effect, as a function of applied field in nearly zero magnetostriction amorphous wires and ribbons have been studied intensively, because of the increasing perspectives of novel applications in magnetic sensors.^{1–3}

The MI effect has a classical electromagnetic behavior where the impedance is changing under the application of a longitudinal magnetic field. The electromagnetic origin of MI effect has been conjectured to the combination of a skin effect and field dependence of the circumferential magnetic permeability associated with the circular motion of magnetic moments.⁴

The impressive sensitivities of a magnetoimpedance effect at room temperature were observed up to 1700%/Oe after proper thermal treatments.⁵ We have found that the maximum magnetoimpedance ratio (MIR) of amorphous $\text{Co}_{66}\text{Fe}_4\text{NiB}_{14}\text{Si}_{15}$ ribbons annealed at 250 °C for 1 h reached to as much as 750% at large current of 60 mA with a high frequency of 5 MHz. Despite MIR is large enough to use for magnetic sensor, the stability of the MI sensors remains questionable. When we measured the magnetoimpedance of this sample several times, we found that MIR was changed slightly at each measurement. Therefore, we have started to investigate the temperature dependence of the MI effect in the sample. The investigation of the temperature dependence of the MI effect seems to be important for scientific interests, technical applications for a temperature sensor, and thermal stability of MI sensors.

In this work, we have used amorphous $\text{Co}_{66}\text{Fe}_4\text{NiB}_{14}\text{Si}_{15}$ (Metglas 2714A) ribbon, which is a well known amorphous ferromagnet with a nearly zero magnetostriction constant and a high magnetic permeability, to study the temperature dependence of MI effect at low temperature (10–300 K).

II. EXPERIMENT

The MI measurements were carried out along the ribbon axis with longitudinal magnetic field. The sample was cut out 15 mm in length and 2.5 mm in width with 19 μm in thickness. The schematic diagram of MI measurement system is shown in Fig. 1. The sample was attached in the cold finger of a closed cycle cryostat (10–300 K). For the four-terminal MI measurement, a silver paint has been used to attach the terminals where the separation between the current leads and the voltage leads are about 15 and 10 mm, respectively. A computer controlled rf signal generator with its power amplifier was connected to the sample in series with a resistor for monitoring the driving ac current. An ac current and a voltage across the sample for calculating the impedance, can be measured by digital multimeters (DMM) with rf/V probes. The external field applied by a solenoid on the top of a cryogenic chamber can be swept through the entire cycle equally divided by 800 intervals from –150 to 150 Oe. Averaging MIR with sweeping fields, changing frequencies,

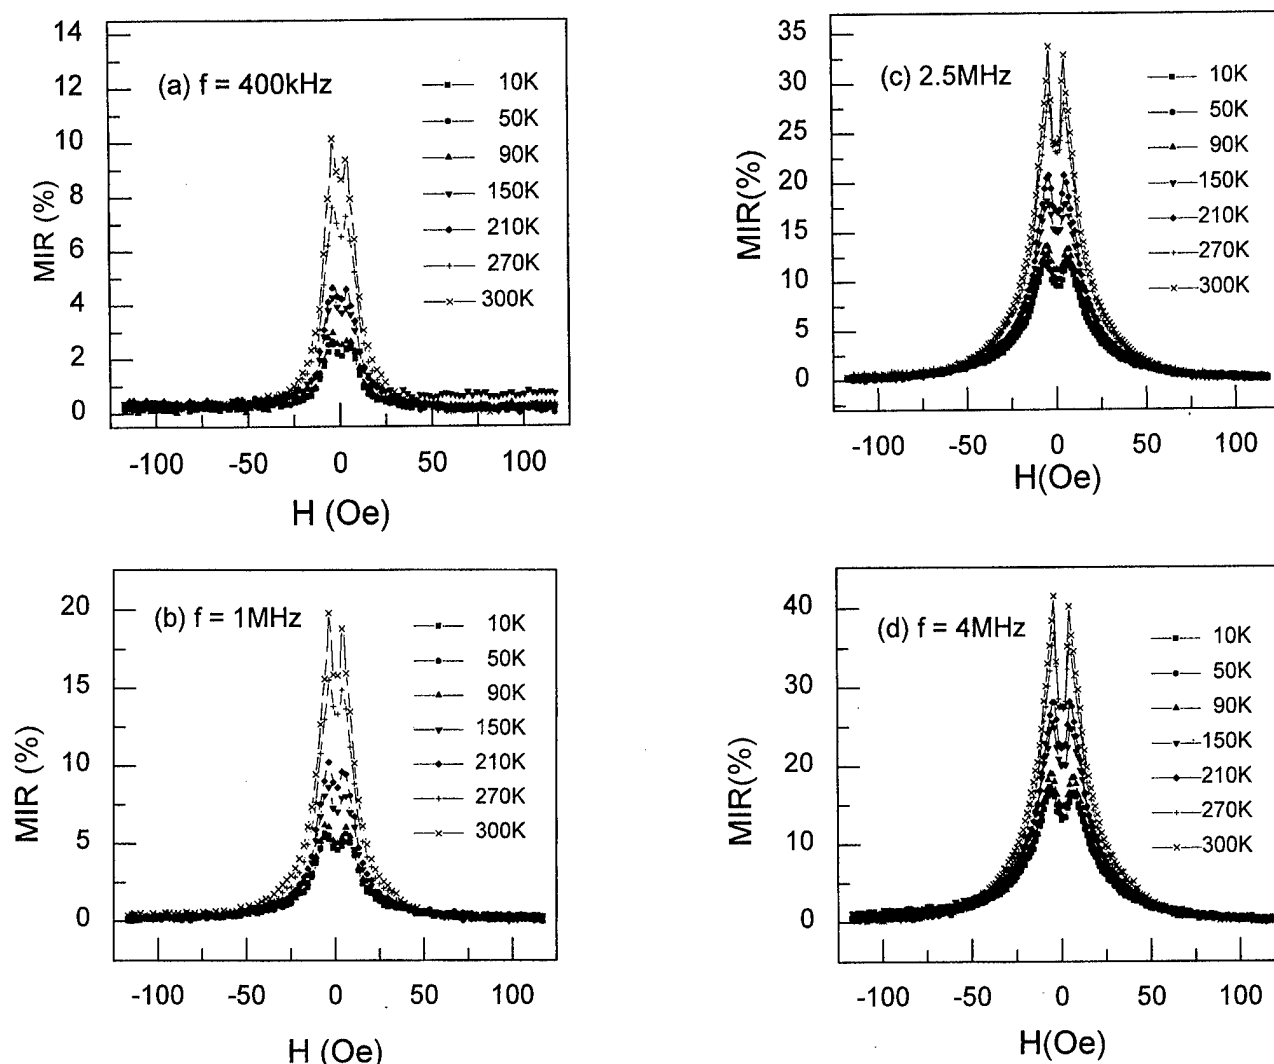

FIG. 2. The MIR vs the external field H for various temperatures at the frequency of (a) 400 kHz, (b) 1 MHz, (c) 2.5 MHz, and (d) 4 MHz.

and keeping a constant ac current, are activities performed by a Windows 95 program. Because of capacitive interferences between wires in the cryogenic chamber, the measured MI values diminished by a factor. The effect of the earth's magnetic field has been minimized by suitable positioning of the sample.

III. RESULTS AND DISCUSSION

The MIR can be defined as $MIR(H) = \Delta Z / Z(H_{\max}) = 1 - |Z(H)/Z(H_{\max})|$, where H_{\max} is an external magnetic field sufficient for saturating the magnetoimpedance. $H_{\max} = 150$ Oe was taken in our experiment.

The frequency dependence of MIR in the sample has shown a typical behavior where the maximum values of MIR are increased and also the shapes of MIR curves are getting broader with the increment of the frequency as observed in the Co-based amorphous wires and ribbons.¹

The MI effect at a high frequency can be explained in terms of an external field dependence of impedance as a result of the transverse magnetization with respect to the current direction flowing through the sample, and the skin effect of an ac current. Because an alternating current tends to be

concentrated near the surface of a conductor, the impedance Z is changing according to the current distribution and the shape of a conductor. For magnetic materials, the transverse circumferential permeability μ_ϕ affects the penetration depth since in magnetic materials it depends on permeability; $\delta_m = \delta / \sqrt{\mu_\phi}$, where δ is $c / \sqrt{2\pi\omega\sigma}$ nonmagnetic penetration depth.⁶ We can expect that with increasing frequency the dependence of the impedance, in case of a skin effect $a/\delta_m \gg 1$, is proportional to $(\omega\mu_\phi)^{1/2}$.

The experimental results are plotted selectively in Fig. 2 due to lack of space. As shown in the Fig. 2, MIR is increasing as frequency increases and MIR is decreasing rapidly as the external field increases producing the bell-shaped curves coincided with the above discussion. Since H_{ex} is a hard axis field with respect to the circumferential anisotropy, the magnetic field applied along the ribbon axis suppresses the circular magnetization by domain wall movements at low frequency regions, or the motion of localized magnetic moments at high frequency regions. Our experiment was performed in the high frequency region (100 kHz–10 MHz) where domain wall movements are highly damped by eddy currents. As the circumferential permeability decreases rap-

FIG. 3. Temperature dependence of maximum MIR values at various frequencies.

idly with the increment of the external field, it is responsible for MI effects in ribbons.

This process accompanied by rapid reduction in the circumferential soft magnetic properties of amorphous $\text{Co}_{66}\text{Fe}_{4}\text{NiB}_{14}\text{Si}_{15}$ ribbons as the external field increases affects the voltage across the ribbon ends. Therefore MIR can be measured directly from the changes of this voltage.

The ac current flowing through the sample generates an easy axis driving field which causes a circular magnetization field H_ϕ . The external longitudinal field H_{ex} is a hard axis field with respect to circular flux change. Therefore, MIR is linearly proportional to the driving current and becomes saturated at a current larger than about 65 mA due to the saturation of the circular magnetization M_ϕ .

One may adapt a model for the transverse biased permeability in thick ferromagnetic films where eddy current damping and the ripple field H_R incorporating with the anisotropy field H_K give rise to the peak of permeability at an external field as well as the broadening of the permeability changes as a function of the external field to explain broadening MIR curves at high frequency.⁷ It is worthily noting that the magnetoimpedance is increasing as frequency increases because the impedance is proportional to $(\omega\mu_\phi)^{1/2}$ even in case of the decrement of the transverse permeability at high frequency. The ripple field can give us further explanation of the changes in the field at the MIR peak with the increment of the current frequency.

The MIR values measured at room temperature are usually 2–3 times larger than the data measured at 10 K for all measured frequencies. For the comparison of MIR curves at different temperatures, the driving currents were fixed at 10 mA. The shapes of the MIR curves were not changed at temperature variation except MIR values. Especially, the changes of the field at the peak MIR curves were not sensitive to the variation of temperature indicating that the anisotropy field H_K was not function of temperature.

The temperature dependance of maximum MIR values at various frequencies are shown in Fig. 3, where the MIR values are increased exponentially as the temperature increases.

FIG. 4. Temperature dependence of maximum MIR values plotted in logarithm graphs for the frequency of (a) 700 kHz and (b) 2.5 MHz.

The maximum MIR values vs temperatures are plotted in a logarithm graph as shown in Fig. 4. The measured $\text{MIR}(T)$ data are very well fit with the function $\text{MIR}(T) = \text{MIR}(0)\exp(cT^2)$, where $\text{MIR}(0)$ is MIR at $T=0$ K and c is the constant.

Because the magnetic permeability is sensitive to the temperature, the MIR is changing rapidly as a function of temperature. The exchange energy between magnetic moments at low temperature is larger than that at high temperature. Therefore, the circular motion of magnetic moments will be frozen at low temperature resulting in lower permeabilities thereby reducing MIR values. Further research should be done for the exact explanation of the exponential increment of $\text{MIR}(T)$.

I. INTRODUCTION

The change in the high frequency impedance of very soft ferromagnetic materials upon the action of external dc fields, has been intensively studied over the last few years.^{1–3} This effect, known as magneto-impedance (MI) is attractive for technological applications, as it combines the appearance of large changes of the impedance ratio for applied fields of few kA/m in strength,² opposite to magnetoresistance effect,⁴ where large fields are required to achieve very small variations of the resistance. The giant magneto-impedance (GMI) effect is interpreted as arising from a classical electrodynamic origin^{2,3} depending on the interaction between the magnetic field created by the ac current flowing through the sample and its magnetic domain structure. When the frequency of the current becomes high enough, the skin effect plays an important role,⁵ diminishing the effective section of the conductor and thus increasing its impedance. As the skin effect depends on the circular magnetic permeability, the sensitivity of the impedance of the sample to the action of an external field can be explained in terms of the variations of this circular permeability.

GMI has been measured in a wide range of materials, with particular interest focused on amorphous and nanocrystalline wires, ribbons, and films.^{6–8} The highest MI effect is observed for Co-rich amorphous wires, with nearly zero magnetostriction constant, where the internal stresses distribution created during quenching couple with magnetostriction to generate a relative small circular anisotropy and a circular domain pattern which enhances the value of the circular permeability. In this work we present measurements of the MI effect in commercially produced wires made with Carpenter HyMu80® alloy (Ni₈₀Mo_{4.2}Fe_{bal} permalloy). This magnetically soft alloy wire exhibits quite interesting properties regarding its magnetization processes.⁹ MI variations as high as 150% are reported, and the evolution of MI ratio with different treatments is also analyzed.

II. EXPERIMENT

Magneto-impedance measurements have been carried out in commercial Carpenter HyMu80® wires (nominal composition Ni₈₀Mo_{4.2}Fe_{bal}). Three different samples were used for the experiment, obtained submitting the initial as-cast wire to different treatments. The initial as-cast sample is produced with a diameter of 140 μm, but does not show good soft magnetic properties and special treatments are then required in order to observe magneto-impedance effect. Sample A is obtained after annealing the as-cast sample at 925 °C for 40 min in a dry H₂ atmosphere, followed by fast cooling. The diameter of the wire can be reduced to 44 μm if a cold-drawn process is carried out in the as-cast wire, leading to sample B. Further annealing of this sample is applied to obtain sample C. In each case, pieces of 20 cm length were chosen for the experiment.

Measurements were carried out in a specially designed experimental setup, similar to one described elsewhere.¹⁰ Impedance variations with respect to a dc-magnetic field are determined by measuring the voltage drop over the sample when an ac current is flowing. Frequency range analyzed sweeps from 1 to 10 MHz. The current intensity is kept constant and equal to 10 mA (rms value) by monitoring the voltage drop over a high frequency resistance connected in series with the sample. Data are acquired using a HP3589A Spectrum Analyzer. An external Helmholtz coil system is used to apply dc magnetic fields up to 11 kA/m parallel to the axis of the sample. The magneto-impedance ratio, which depends on the applied magnetic field, is defined as $\Delta Z/Z(H) = 100 \times [Z(H) - Z(H_{\max})]/Z(H_{\max})$, where H_{\max} is the maximum applied magnetic field. The system is computer controlled through a GPIB interface.¹⁰ Quasistatic hysteresis loops have been measured using a conventional induction technique.

III. RESULTS AND DISCUSSION

Sample A has a characteristic loop of a soft magnetic material with a coercivity of 15 A/m, while in sample B a significant hardening was observed, with an increase of the coercive field up to 400 A/m as a consequence of the cold

^{a)}Electronic mail: VAZQUEZV@FENIX.IMA.CSIC.ES

^{b)}Present Address: YBM Magnex Inc., 110 Terry Drive, Newtown, PA 18940.

FIG. 1. Quasistatic axial hysteresis loops for cold-drawn sample (sample B).

drawing process that induces quite strong stresses in the sample. Figure 1 shows the hysteresis loop measured in this sample. Further annealing on sample B results in a decrease of the coercivity to a value of 30 A/m in sample C as a consequence of the significant relief of the internal stresses. A common feature of all the loops (samples A, B, and C) is their quasibistable magnetic behavior: there is a critical field below which it is not possible to observe remagnetization. Above this field, hysteresis loops appear, as shown in Fig. 1. This behavior, typical of amorphous wires, can be explained considering that the main contribution to the magnetization process arises from domain wall motion.

GMI measurements for samples B and C are shown in Fig. 2, where the relative variation in the impedance, $\Delta Z/Z$, is plotted as a function of the applied magnetic field. Different curves correspond to different frequencies of the ac current, in the range from 1 to 10 MHz. The general trend is the decrease of $\Delta Z/Z$ for increasing dc field as a consequence of the decrease of the circular permeability.²

The largest MI ratio of 150% is found for sample C, at a frequency of 3 MHz, while the maximum variation of sample B is of 50% and takes place at a higher frequency of 7 MHz. Results for sample A (not shown) are very similar to those of sample C. For this sample, a maximum value of 130% is found at 1 MHz.

FIG. 2. Variations of the impedance of samples B (a) and C (b) with axial magnetic field for different frequencies.

FIG. 3. (a) Evolution with frequency of the maximum value of MI ratio with the frequency of the ac current and (b) evolution of the magnetic field H_{peak} where the maximum of the MI ratio takes place as a function of the frequency of the current.

The fact that sample B shows a smaller GMI ratio than samples A and C can be explained in terms of the relative magnetic softness of each sample. It is anyway remarkable the large magneto-impedance effect of sample B in spite of its much larger coercivity. As is well known, MI depends on variations of the circular permeability induced by external axial fields. These changes modify the penetration depth of the ac current and then the impedance of the sample. A softer magnetic material will, in general, present a higher variation of the circular permeability.

The evolution of the field dependence of the impedance with frequency is a common feature of all measurements performed. The maximum value of MI ratio changes with the frequency of the ac current as shown in Fig. 3(a). Samples B and C show a maximum located at 4 and 7 MHz, respectively, while sample A reaches its maximum for the lower frequency considered.

The magnetic field where the maximum value of the impedance is measured (H_{peak}) also changes with frequency. The initial peak, located at $H=0$ (for sample A), evolves into two symmetric peaks which tend to move towards higher values as the frequency increases. The same tendency has been observed for the three samples under consideration. This effect can be seen in Fig. 3(b).

The maximum in the MI ratio is usually explained in terms of the existence of a circular anisotropy. For a fixed value of the external field (equal to the anisotropy field), the anisotropy is compensated, and a maximum in the permeability (and then in the MI ratio) is expected. The observation of this maximum in wires with a bistable behavior indicates that domain wall motion cannot be the only mechanism taking part in the magnetization process, as could be deduced from the shape of the hysteresis loops (Fig. 1). Instead, magnetization rotation from the circular to the longitudinal direction must be considered, as pointed out by Atkinson and Squire,¹¹ in order to account for a variation in the circular permeability of the sample.

On the other side, the shift of the maximum towards higher fields as the frequency increases [Fig. 3(b)] can be explained considering the existence of a radial anisotropy profile in the wire. An increase in the frequency is associated with a decrease in the penetration depth of the ac current through the sample. Then, for very high frequencies, the current is flowing only through a layer close to the surface of the material. As the transport properties (impedance in this case) depend on the behavior of this region of the material, the measurement of the impedance allows us to get information of the region close to the surface. The observed increase with frequency of the field where MI ratio is maximum (the circular anisotropy field) can be explained considering that the anisotropy is not homogeneous in all the wire section, but increases as one approaches the surface. As the local anisotropy is higher, the peak moves toward higher values. For very high frequencies, the anisotropy can be so large that the maximum applied field is not enough to saturate the sample. In this case, the impedance can have a smaller value for $H = 0$ than for $H = 11$ kA/m. This is the case observed for sample C at 10 MHz.

IV. CONCLUSION

High values of MI are reported for a Ni-rich permalloy wire presenting a quasibistable behavior. The analysis of the frequency evolution of the curves reveals the existence of a

radial profile of anisotropies, and proposes MI measurements as a useful tool to study the magnetic behavior of regions close to the surface of the wire.

The correlation between magnetic anisotropy and magnetoimpedance has been studied in field- and stress-annealed Fe_{73.5}Cu₁Nb₃Si_{13.5}B₉ ribbons. As-cast and previously nanocrystallized samples were submitted to different annealing conditions ($T=500, 530$, and 560°C and tensile stress $\sigma=150$ MPa) in order to induce different magnetic anisotropy. The magnetoimpedance ratio $[\Delta Z/Z]$ was measured at 3 MHz using a driving current $I_{\text{rms}}=10$ mA. An hysteretic behavior of the magnetoimpedance ratio is observed. This hysteretic behavior is interpreted considering the magnetization process for samples exhibiting different magnetic anisotropies. © 1998 American Institute of Physics. [S0021-8979(98)39511-0]

INTRODUCTION

It is well known that a suitable annealing ($T=540^\circ\text{C}$, $t=1$ h) of the amorphous FeSiBNbCu alloys (known as FINEMET) leads to a nanoscale grain-size multiphase structure, which has excellent soft magnetic properties.^{1,2} A magnetic anisotropy can be induced if this annealing is performed under the application of a magnetic field, an external stress, or both of them.³⁻⁵

The so-called giant magnetoimpedance (GMI) has been extensively studied in the last few years due to its technological impact.^{6,7} This effect arises from a field-induced change in the classical skin depth that follows the changes in the magnetic circular permeability when a high-frequency current flows through the sample. The effect is also sensitive to the anisotropies of the material and can exhibit hysteretic behavior.⁸⁻¹⁰ Some results on the giant magnetoimpedance of field-annealed FINEMET ribbons were presented recently,^{6,10} but up to now an analysis of the role of field and stress annealing for the GMI ratio, i.e., of induced anisotropies, to the best of our knowledge is still missing.

The aim of this paper is to study the influence of different heat treatments, like field and/or stress annealing, on the giant magnetoimpedance in Fe_{73.5}Cu₁Nb₃Si_{13.5}B₉ samples and its hysteretic behavior. The results show that the hysteretic behavior is related to the irreversible magnetization processes of the samples.

EXPERIMENTAL PROCEDURE

Amorphous ribbons of the composition Fe_{73.5}Cu₁Nb₃Si_{13.5}B₉ were prepared by a conventional melt spinner. The dimensions of the samples chosen for magnetic measurements were 100 mm×0.2 mm×18 μm . Field an-

nealing was done in two regimes: (i) IF: annealing of as-cast samples for 1 h at 540°C with a magnetic transverse field of 240 kA/m, and (ii) IIF: annealing the as-cast samples for 1 h at 540°C and subsequent annealing at the same conditions but under a magnetic transverse field of 240 kA/m. Stress annealing was carried out in a vertical furnace as described in detail elsewhere.⁴ The sample is suspended inside a furnace and a load is fastened to the ribbon edge using a special clamp. This stress annealing was also performed in two ways: (i) IS: annealing of an as-cast sample at $T=530^\circ\text{C}$ for $t=2$ h under a tensile stress of $\sigma=150$ MPa, and (ii) IIS: using a previously nanocrystallized sample (annealed at $T=530^\circ\text{C}$, $t=1$ h) and then submitting this sample to a stress annealing at temperatures $T=500, 530$, and 560°C under a tensile stress of $\sigma=150$ and 290 MPa. Samples annealed $T=530^\circ\text{C}$ for $t=1$ h without field or stress (conventional annealing) were also used.

Hysteresis loops of the samples were measured by the conventional flux method. The anisotropy constants induced by field or stress annealing, K_u , were deduced from the axial hysteresis loops as $K_u = \mu_0 M_s H_k / 2$, where $\mu_0 M_s$ is the saturation magnetic polarization and H_k is the anisotropy field. The magnetoimpedance was measured using a fully computer-controlled setup.¹¹ The change of ac impedance of the sample was evaluated by measuring the ac voltage drop across the sample while passing a constant ac current through it. The GMI ratio was defined as $\Delta Z/Z(H) = 100 \times [Z(H) - Z(H_{\text{max}})]/Z(H_{\text{max}})$, for a maximal field $H_{\text{max}} = \pm 10.5$ kA/m. The constant current $I_{\text{rms}}=10$ mA was supplied by a HP 3589A spectrum/network analyzer and the frequency was fixed at 3 MHz. The axial dc field was produced by a pair of Helmholtz coils.

In all the cases here discussed, the annealings induce a transverse magnetic anisotropy besides the magnetic softening (i.e., coercivity) typical of the nanocrystallization process of those samples.

FIG. 1. (a) Hysteresis loops and (b) giant magnetoimpedance ratio ($\Delta Z/Z$) measured in field- (IF and IIF) and conventional- (conv.) annealed $\text{Fe}_{73.5}\text{Si}_{13.5}\text{B}_9\text{Nb}_3\text{Cu}_1$ ribbons.

RESULTS AND DISCUSSION

Figure 1 shows the hysteresis loops and GMI ratio curves for the samples after IF and IIF annealings, and also after the conventional one. Both treatments in a magnetic field induce a transversal magnetic anisotropy, the one corresponding to annealing in one step (IF) being higher than that in two steps (IIF). The GMI curve for the conventional annealing shows a maximum about 15% with a typical GMI behavior. The IF annealing gives rise to a nonhysteretic GMI curve with maximum $\Delta Z/Z$ of about 19% for an applied dc field of ± 300 A/m, which corresponds to the anisotropy field H_k of this sample. The IIF annealing promotes $\Delta Z/Z$ values as large as 28%, with a GMI curve characterized by a two-peak shape and its hysteretic character. Although the obtained GMI value is higher, the observed hysteresis may be unsuitable for technological applications.

Figure 2 shows the axial hysteresis loops and GMI curves after IS and IIS stress annealing. In this case, the higher the temperature of the stress annealing the higher the value of the induced magnetic anisotropy and the coercive field. IS annealing leads to the state with a smaller GMI ratio (about 7.5%) and also shows a hysteretic behavior in the field interval ± 1.5 kA/m.

The hysteresis of the GMI is observable exactly within the same field region as the axial hysteresis (see the hysteresis loop in Fig. 2).^{9,12} Figure 3 shows the hysteresis of the GMI ratio observed for the sample submitted to IIS at 560 °C.

These curves can be explained considering the corresponding magnetization processes that take place in the samples. The samples are submitted to two kinds of magnetic fields, i.e., the ac field generated from the ac current flowing for the GMI measurement and the superimposed dc axial field to the last one. At the saturation, the dc field determines the magnetization direction, and the ac field has only a minor role, being unable to affect the magnetization vector inside the sample. When the dc field is decreased, the magnetization starts to sense the presence of the ac field, and

FIG. 2. (a) Hysteresis loops and (b) giant magnetoimpedance ratio ($\Delta Z/Z$) measured in stress-annealed $\text{Fe}_{73.5}\text{Si}_{13.5}\text{B}_9\text{Nb}_3\text{Cu}_1$ ribbons according to procedures IS and IIS. Open and solid symbols in (b) refer to decreasing and increasing field, respectively.

the magnetization vector starts to rotate, increasing thus the circular permeability, and thus the impedance. When the anisotropy field is reached, the magnetization vector is more free to rotate under the influence of the ac field, and the circular permeability exhibits a maximum. At this point, there is a maximum in the GMI. As the field is further decreased, domain-wall irreversible processes start to take place, as clearly seen by the axial hysteresis loops, which results in irreversible contributions to the circular magnetization processes, and thus, a hysteretic GMI can be observed. The different GMI behavior of the different samples can be explained considering that the differences in the induced an-

FIG. 3. (a) Hysteresis loop and (b) GMI ratio ($\Delta Z/Z$) measured in a stress-annealed $\text{Fe}_{73.5}\text{Si}_{13.5}\text{B}_9\text{Nb}_3\text{Cu}_1$ ribbon according to procedure IIS. Open and solid symbols in (b) represent decreasing and increasing field, respectively.

isotropy, imposed by the distinct annealing conditions, produce specific domain structures with particular magnetization processes and GMI.

In view of this, magnetoimpedance measurements can be considered as a valid and alternative tool to investigate the magnetic behavior of ferromagnetic samples. On one side, it is possible to obtain information on the efficiency of different annealing methods to induce transverse anisotropy. On the other side, the appearance of hysteresis in the GMI curves denotes the irreversibility of the dynamic process of circular magnetization. As shown in Fig. 3, the magnetic field where hysteresis in the impedance appears, roughly corresponds with the field where hysteresis in the axial magnetization is found. Thus, this irreversibility, associated with the behavior of the circular permeability under the action of an axial field, can be studied through the analysis of the shape of the GMI curves.

CONCLUSIONS

Transverse magnetic anisotropy induced by different field and stress annealing in nanocrystalline FINEMET changes the domain structure, modifying the magnetization processes and the GMI behavior. Field annealing at 540 °C for 1 h combined with nanocrystallization produces a transversal anisotropy with $K_u = 75 \text{ J/m}^3$, which is characterized by nonhysteretic magnetoimpedance curves. Field annealing on previously nanocrystallized samples produce higher GMI values, but extremely hysteretic in the field interval applied during the measurements.

Stress annealings at 500, 530, or 560 °C with tensile stress $\sigma = 150 \text{ MPa}$ for 1 h give rise to a higher stress-induced magnetic anisotropy but a smaller GMI maximum ratio. All these states are characterized by a hysteretic GMI in the low-field region near zero field, where some irreversibility of the magnetization process appears. It was found

also that for the higher stress-induced magnetic anisotropy, a more complex shape of the GMI curves is observed, with a final appearance of additional peaks in a field which nearly corresponds to the point of the inflection of the axial hysteresis loop. Maximum $\Delta Z/Z$ was always observed for applied dc fields corresponding to the induced anisotropy field. Hysteretic behavior of the magnetoimpedance in nanocrystalline FINEMET ribbons after different regimes of dc field and stress annealing can be a critical parameter from the point of view of technological applications of this material as GMI sensors.

Giant magneto-impedance effect in nanocrystalline glass-covered wires

H. Chiriac,^{a)} T. A. Óvári, and C. S. Marinescu

National Institute of R&D for Technical Physics, 47 Mangeron Boulevard, 6600 Iași 3, Romania

We investigate the evolution of the magneto-impedance (MI) response of $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$ glass-covered wires with the annealing temperature, starting from the as-cast amorphous state up to 600 °C. As-cast FeCuNbSiB amorphous glass-covered wires display a MI ratio of about 1%, this value increasing with the annealing temperature to about 5% for 550 °C when the nanocrystalline phase appears. For wires which have had the glass removed, the MI ratio increases from 5% for the as-cast amorphous state up to 28% after the appearance of the nanocrystalline phase. The MI is larger than that found in CoFeSiB amorphous wires after glass removal. Annealing over 550 °C leads to a decrease of the MI ratio for both glass-covered samples and samples with the glass coating removed. The results demonstrate the role of soft magnetic properties on the sensitivity of the MI effect. © 1998 American Institute of Physics. [S0021-8979(98)51111-5]

I. INTRODUCTION

The giant magneto-impedance (GMI) effect, that consists of a variation of the high frequency impedance of a magnetic conductor when it is subjected to a dc magnetic field, was extensively studied over the last few years and was found to be useful for sensing applications.^{1,2} The largest GMI effect was obtained in $\text{Co}_{68.15}\text{Fe}_{4.35}\text{Si}_{12.5}\text{B}_{15}$ amorphous wires with diameters reduced down to 30 μm by cold drawing in several steps. The wires were subsequently tension annealed in order to obtain a circumferential domain structure in the entire volume, since it was shown that this is the most favorable case for a sensitive GMI response.¹ The impedance behavior is strongly related to the basic magnetic properties of the materials, and to the changes in the dynamic magnetization processes as the frequency increases.

The aim of this article is to study the sensitivity and magnitude of the GMI effect in $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$ nanocrystalline glass-covered wires. Changes induced when the glass coating is removed by chemical etching are also considered. The results are discussed by taking into account the specific magnetic properties and behavior of these wires.

The results obtained are important from the point of view of the applications of these materials in magnetic sensors working on the GMI principle.

II. EXPERIMENT

We prepared $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$ amorphous glass-covered wires by glass-coated melt spinning. For our experimental investigations we have chosen wires with a metallic core diameter of 15 μm and a glass cover thickness of 5 μm . The amorphous state was checked by x-ray diffraction. $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$ amorphous glass-covered samples and samples obtained after glass removal were annealed in vacuum for 1 h at temperatures up to 600 °C. Each stage of annealing was performed starting from an amorphous wire, which was annealed for 1 h at a given annealing temperature, T_a , e.g., 500, 550 °C, etc.

GMI measurements were performed on glass-covered samples and on samples after glass removal after each stage of annealing at frequencies up to 10 MHz, using a digital oscilloscope coupled with a computer that allowed data acquisition and processing. We studied the impedance behavior as function of frequency, f , and axial dc field, H_{dc} .

III. RESULTS AND DISCUSSION

We analyze in the following the sensitivity of the GMI effect in FeCuNbSiB glass-covered wires and wires after glass removal, starting from the amorphous state after different stages of annealing. Figure 1 shows the frequency dependence of the MI ratio, $\Delta Z/Z$, defined as $[Z(H_{dc}=0) - Z(H_{dc}=1000 \text{ A/m})]/Z(H_{dc}=0)$, where Z is the impedance for glass-covered FeCuNbSiB wires with the annealing temperature, T_a , as a parameter.

FIG. 1. Frequency dependence of the magneto-impedance ratio, $\Delta Z/Z = [Z(H_{dc}=0) - Z(H_{dc}=1000 \text{ A/m})]/Z(H_{dc}=0)$, for glass-covered FeCuNbSiB wires with the annealing temperature as a parameter.

^{a)}Electronic mail: hchiriac@phys-iasi.ro

FIG. 2. Frequency dependence of the magneto-impedance ratio, $\Delta Z/Z$, for FeCuNbSiB wires after glass removal with the annealing temperature as a parameter.

The MI ratio is directly related to the sensitivity of the GMI effect since it indicates the behavior of Z at two extreme values of the axial field H_{dc} : 0 A/m, where Z is affected only by the frequency f of the ac driving current, and 1000 A/m, which is a high value field that completely damps the magnetization processes in the circumferential direction of a soft magnetic wire. The circumferential magnetization processes play a decisive role in determining the magnitude and sensitivity of the GMI effect. The GMI effect is directly related to the magnitude of the skin effect, since the dynamics of the magnetization in the circumferential direction—domain wall movements or rotations—affects the behavior of the circumferential permeability μ_θ , which, in turn, influences the magnetic penetration depth $\delta_m = (\rho / \pi \cdot f \cdot \mu_\theta)^{1/2}$, where ρ is the resistivity of the wire.

One observes that as-cast amorphous FeCuNbSiB displays a GMI effect with a maximum MI ratio of 1%. This very small value of $\Delta Z/Z$ is due to the high positive magnetostriction of amorphous FeCuNbSiB glass-covered wires ($\lambda \approx 25 \times 10^{-6}$) that leads through magnetomechanical coupling with internal stresses to a domain structure with axially magnetized inner core and radially magnetized outer shell. After annealing at 500 °C, the wires become magnetically softer due to stress relief, and the maximum MI ratio increases to about 2%. After annealing for 1 h at 550 °C, the nanocrystalline phase appears,³ and consequently the wires become magnetically softer, the maximum MI ratio increasing to more than 5%. Annealing over 550 °C leads to a dimensional increase of the α -FeSi crystalline grains and consequently to a deterioration of the soft magnetic properties, resulting in a decrease of the maximum MI ratio to less than 4.5%.

Figure 2 shows the frequency dependence of the MI ratio, $\Delta Z/Z$, for FeCuNbSiB wires after glass removal, with the annealing temperature, T_a , as a parameter.

One observes that amorphous FeCuNbSiB wires after glass removal display a maximum MI ratio of 5% before any

annealing. This behavior is expected to be due to the stress relief produced by glass removal. After annealing at 500 °C, the maximum MI ratio increases to about 14% due to further stress relief produced by annealing. Once the nanocrystalline phase appears (annealing at 550 °C), the maximum MI ratio reaches about 28%. Annealing over 550 °C has the same result as that in the case of the glass-covered wires: the good soft magnetic properties suffer deterioration due to the increase in size of the crystalline grains.

Nanocrystalline wires without glass have a much more sensitive GMI response as compared to glass-covered ones since they are magnetically softer (the coercive force is about 100 A/m for the former and almost 400 A/m for the latter). The GMI response of nanocrystalline wires without glass is even better than that of CoFeSiB amorphous wires after glass removal,⁴ with their maximum MI ratio being about 20%. In addition, the maximum MI ratio of nanocrystalline wires after glass removal is obtained at lower frequencies (~ 4 MHz) as compared to CoFeSiB amorphous ones after glass removal (~ 9 MHz). Both aspects can be explained by noting that at high frequencies, where circumferential magnetization is achieved by spin rotations, the differences in the soft magnetic properties from the outer shells of the two materials play an essential role. Thus, in CoFeSiB amorphous wires after glass removal a larger energy, provided by the circumferential ac field, is required in order to rotate the magnetic moments from the easy axis direction toward any other direction, since in this case, the circumferential magnetoelastic anisotropy from the outer shell, determined by the coupling between magnetostriction and large compressive circumferential stresses is important.⁵ On the other hand, nanocrystalline wires without glass are magnetically softer due to their vanishing magnetostriction.³ Thus, a larger μ_θ of nanocrystalline wires without glass, compared to the amorphous ones without glass, is expected. The direct consequence of this fact is a shift toward lower values of the frequency where the maximum MI ratio is detected in nanocrystalline wires, and is a more sensitive effect in this case. Under these circumstances, we can state that good soft magnetic properties are essential in obtaining a sensitive GMI response of a given material. Furthermore, the presence of good soft magnetic properties may be considered as a second criterion in the choice of an appropriate material for a GMI-based application, together with the already widely accepted criterion that requires an appropriate domain structure, e.g., a circumferential one for wires and a transverse one for ribbons and thin films.

This statement is supported by the fact that in the discussed frequency range the sensitivity of the GMI response of nanocrystalline wires after glass removal is very close to that of cold-drawn amorphous CoFeSiB ones.⁴ The tendency of these thin wires (15 μm in diameter) to reach a similar magnitude of the GMI effect ($\sim 28\% - 30\%$) like the cold-drawn ones (30 μm in diameter), emphasizes once again the close relationship between good soft magnetic properties and a sensitive GMI effect, since at close values of the resistivities, it is obvious that the differences in μ_θ play an important role in the magnitude of the skin effect.

The above results allow us to suggest a new application of the GMI effect, namely, its use for directly monitoring the structural changes that occur in amorphous ferromagnets during annealing, and especially those during specific annealing for nanocrystallization.

IV. CONCLUSION

We investigated the GMI effect in $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$ nanocrystalline glass-covered wires and wires after glass removal. Nanocrystalline wires without glass display the more sensitive GMI response. The results are explained by considering the structural changes that occur during annealing and their effect on the magnetic properties of both glass-covered wires and wires after glass removal. The results obtained

indicate the importance of good soft magnetic properties for a sensitive GMI response. Our study is important with regard to the selection of a proper material for the achievement of GMI-based magnetic sensors.

High frequency properties of glass-coated microwire

A. N. Antonenko,^{a)} E. Sorkine, A. Rubshtein, V. S. Larin,^{b)} and V. Manov

Advanced Metal Technologies Ltd., 1 Ha'atmaut St., P.O.B. 2903, Even Yehuda 40500, Israel

Static and high-frequency 1–30 MHz properties of the $(\text{Co}_{100-x}\text{Mn}_x)_{75}\text{B}_{15}\text{Si}_{10}$ microwires cast using the modified Taylor's technique are reported. The hysteresis loop and the frequency dependence of permeability indicate that the longitudinal magnetization process occurs by coherent rotation of the moments. The values of static permeability are in good agreement with those predicted by the theory of ferromagnetic resonance where damping is taken into account. We observed a close correlation between the static permeability and the high-frequency limit (the frequency up to which the real part of permeability is still constant). For glass-coated CoMn microwires, this limit is considerably higher than that given by the Snoek equation. © 1998 American Institute of Physics. [S0021-8979(98)39611-5]

INTRODUCTION

Glass-coated amorphous microwires, cast by a modified Taylor's technique is a comparatively scarcely studied magnetic material. Hereafter, we will adhere to the term "microwire" to distinguish this material from amorphous wires produced by other methods, for example, by rotating water quenching. Recently, several papers devoted to the investigation of microwires were published.^{1,2} It was shown that microwires demonstrate unique magnetic properties. In particular, Fe-based microwires with positive magnetostriction demonstrate bistable behavior, with the critical length as small as 2 mm.² The natural ferromagnetic resonance in the 2–12 GHz frequency range was observed in Fe-based microwires.³ The permeability of microwires reaches an extremely high value (up to 1000) in this frequency range, that suggest that microwires may be a promising material for super-high-frequency applications.

Co-based microwires with negative magnetostriction are studied very scarcely. Static magnetic properties of such microwires were reported in Ref. 4. The investigation of the GMI effect indicates that Co-based microwires have a high permeability in a radio-frequency range of 1–100 MHz, however, there are no relevant publications relating to the direct measurement of permeability in this frequency range.

The present work reports the measurement of the complex permeability of Co-based microwires in the 1–30 MHz frequency range. The correlation between static and high-frequency magnetic properties of microwires are studied too. Another aspect of this work is an attempt to provide a theoretical description of microwire behavior. The dynamic behavior of a magnetic material such as ferrite or amorphous ribbon is rather complicated. In high-frequency magnetic fields, both moment rotation and domain wall motion can take place. Calculations of permeability and of energy losses with different modes of remagnetization are extremely difficult. From this point of view, the microwire seems to be

easier to model. Unlike other materials, it is possible to use a simple model for the description of its dynamic properties.

EXPERIMENT

We have investigated microwires of $(\text{Co}_{100-x}\text{Mn}_x)_{75}\text{B}_{15}\text{Si}_{10}$ alloys, where x lies in the range from 4 to 8. In this range of Mn content, the alloy magnetostriction passes through zero. The microwires were cast by Taylor's technique. The diameter of the metal was in the 6–10 μm range, and the glass coating was 2–4 μm thick.

We have measured static hysteresis loops as well as real and imaginary parts of the permeability in the 1–30 MHz frequency range. The static hysteresis loop was plotted using a conventional hysteresisgraph. The microwire was placed in the alternating magnetic field of a long solenoid. A signal proportional to the solenoid current was applied to the X channel of an oscilloscope, while remagnetization signal was detected by a small pickup coil and, after integrating, was applied to the Y channel.

The permeability was measured at high frequency using the LC resonance method. First, the circuit with a coreless coil was adjusted to resonance at certain frequency by changing the capacitance. The value of the capacitance, C_1 and the quality factor, Q_1 were measured. The sample consisting of several microwires was placed into the coil, and then the circuit was adjusted to resonance again by changing the value of the capacitor. The new values, C_2 and Q_2 , were measured. Real and imaginary parts of permeability were calculated as follows:

$$\mu' = 1 + \left(\frac{C_1}{C_2} - 1 \right) \cdot \frac{D^2}{nd^2}, \quad (1)$$

$$\mu'' = \left(\frac{1}{Q_2} - \frac{1}{Q_1} \right) \cdot \frac{D^2}{nd^2}, \quad (2)$$

where D is the diameter of coil, d is the diameter of microwire core, and n is the number of microwires.

The static hysteresis loop depends substantially on the Mn content of the microwire material. Mn-rich microwires feature a rectangular hysteresis loop. With decreasing Mn

^{b)}«AmoTec» Ltd, bd Dachia 15/78, 2038 Kishinev, Moldova.

FIG. 1. The typical hysteresis loop of microwire with Mn<6%.

content, the value of coercivity decreases and the loop becomes gradually unhysteretic. Further decreasing of the Mn content does not change the shape of the loop, only its slope, which decreases. The anisotropy field of the material thus increases with the decreasing in the Mn content. The typical loop of microwires with less than 6% Mn is presented in Fig. 1. This loop has an inflection point approximately corresponding to the anisotropy field H_k .

The frequency dependences of real and imaginary parts of the permeability for different values of the anisotropy field are presented in Figs. 2 and 3. The real part of permeability is nearly constant in a certain frequency range, and it decreases rapidly as the frequency increases over a critical value f_r . The frequency dependence of the imaginary part shows a maximum at f_r . The static permeability as well as f_r depend on anisotropy field H_k . Table I summarizes the obtained results.

DISCUSSION

The hysteresis loops we obtained are typical for the case of an external magnetic field applied perpendicular to the plane of easy magnetization. In our experiments, this plane is perpendicular to the microwire axis. The magnetic anisotropy is induced by the stresses quenched in the microwire core. These stresses arise during the process of microwire

FIG. 2. Frequency dependence of the real part of the permeability. The symbols mean experimental data, continuous curves were obtained from the proposed model.

FIG. 3. Frequency dependence of the imaginary part of the permeability. The symbols mean experimental data, continuous curves were obtained from the proposed model.

fabrication as a result of difference in thermal expansion coefficient between glass and metal. As shown in Ref. 5, the value of internal stresses σ may reach 1 GPa. If the Mn content is lower than approximately 6%, the magnetostriction constant λ becomes negative. Due to the effect of magnetoelastic anisotropy, which is proportional to $\lambda\sigma$, the moments will lie in a plane perpendicular to the microwire axis, and the external magnetic field applied along the microwire axis will produce a coherent rotation of moments.

At present time, there is not a definite picture of the magnetic structure in the Co-based microwires. The appearance of circumferential anisotropy like in the conventional amorphous wires seems to be the most probable, however, there is no direct confirmation of this supposition. Nevertheless, the magnetic properties of microwires may be described without knowing the definite magnetic structure. The further consideration is based on the following assumptions:

(a) The axis of easy magnetization lies in the plane perpendicular to the microwire axis. In each point of microwire the magnetic anisotropy has the same value H_k and magnetization vector \mathbf{M} coincides with the direction of magnetic anisotropy.

(b) The coherent moments rotation is the only mechanism of remagnetization.

The Gilbert equation for this mechanism is⁶

$$\frac{d\mathbf{M}}{dt} = \nu \cdot \left\{ \mathbf{M} \times \left(\mathbf{H} - \frac{\alpha}{\nu M} \cdot \frac{d\mathbf{M}}{dt} \right) \right\}, \quad (3)$$

where \mathbf{M} is the magnetization vector, \mathbf{H} is the magnetic field vector, ν is the gyromagnetic factor, and α is the parameter which describes losses.

TABLE I. μ_{st} is the static permeability and μ'_r , μ''_r is the permeability measured at f_r .

H_k (A/m)	f_r (MHz)	μ_{st}	μ'_r	μ''_r
45	5	8000	4000	3000
120	12	4000	2000	1200
280	25	2500	1200	400
500	30	1000	500	60

The \mathbf{M} and \mathbf{H} vectors include static ($\mathbf{M}_0, \mathbf{H}_k$) and alternating (\mathbf{m}, \mathbf{h}) components and we can write:

$$\mathbf{M} = \mathbf{M}_0 + \mathbf{m}, \quad \mathbf{H} = \mathbf{H}_k + \mathbf{h}. \quad (4)$$

Let us divide the microwire on elements which are small enough to consider that the direction of local anisotropy in each element is uniform. The assumption (b) means that the component m_z has the same value for each element. So, from the solution of Eq. (3) for a small element, it is possible to obtain the permeability of the whole microwire. We take a local coordinate system for a small element of the microwire such that the X axis is directed along the local \mathbf{M}_0 and \mathbf{H}_k vectors, while the Z axis is directed along the microwire axis. The effect of neighboring elements may be taken into account by introducing the demagnetization factor, N , so \mathbf{h} transforms to $\mathbf{h} - N\mathbf{m}$. The components of N for the long cylinder are $N_x = 1/2$, $N_y = 1/2$, $N_z \sim (l/r)^2 \ll 0$ (l is the length of microwire, r is the radius of microwire). We confine ourselves to the consideration of dynamic processes in the low external field, such that $h \ll H_k$ and $m \ll M_0$. So, we may neglect terms including products of mh , mm , and hh . With these assumptions, Eq. (3) may be rewritten as

$$\frac{dm_y}{dt} = \nu \cdot \left[m_z H_k - M_0 h + M_0 N m_z + \frac{\alpha}{\nu} \cdot \frac{dm_z}{dt} \right], \quad (5)$$

$$\frac{dm_z}{dt} = \nu \cdot \left[M_0 N m_y + H_k m_y + \frac{\alpha}{\nu} \cdot \frac{dm_y}{dt} \right]. \quad (6)$$

By solving these equations, it is possible to find an expression for the frequency-dependent complex permeability:

$$\tilde{\mu} = \mu_{st} \cdot \frac{\omega_r (\omega_r (1 + \mu_{st} N) + i \omega \alpha)}{\omega_r^2 (1 + \mu_{st} N) - \omega^2 - \omega^2 \alpha^2 + 2i \omega \omega_r \alpha (1 + \mu_{st} N)}, \quad (7)$$

where $\omega_r = \nu H_k$, $\mu_{st} = M_0 / H_k$ (initial permeability).

The term $(\alpha/\nu) \cdot (dm_z/dt)$ in Eq. (5) expresses the demagnetization field occurring due to eddy currents. According to Ref. 7 the moment rotation in the cylinder of radius r induces a demagnetization field $H_d = (r^2/4\rho) \cdot (dM/dt)$. The loss factor α is equal to $(\nu M r^2)/4\rho$, where ρ is the resistivity of the microwire. The frequency dependences of the real and imaginary parts of the permeability are presented in Figs. 2 and 3. These were calculated using the following parameters:

$$r = 4 \times 10^{-6} \text{ m}, \quad \rho = 1.6 \times 10^{-6} \Omega \text{ m},$$

$$M = 0.8 \text{ T}, \quad \text{and} \quad \nu = 2.2 \times 10^5 \text{ m(A s)}^{-1}.$$

The experimental results obtained are in a good agreement with the above theoretical considerations. The experimental values of static permeability and permeability at the critical frequency, as well as the values of critical frequency differ less than 20% from the values predicted by the proposed theoretical model. It is worth to note that CoMn microwires show a lower value of μ_r'' than that predicted by the theoretical model especially for the alloys with high anisotropy field. It is also interesting that a certain part of the frequency dependence of μ_r' lies above the so-called Snoek limit line which is described by the equation $\omega\mu = 2\nu M/3\mu_0$.⁸ The Snoek line confines the area in which the dependences $\mu(f)$ would lie if we take a bulk material with a single magnetic anisotropy. There are two kinds of considerably different magnetic anisotropies in the microwire. A rather low magnetoelastic anisotropy is responsible for the high value of static permeability while a strong shape anisotropy provides the extension of the frequency range where the real part of the permeability stays near constant.

CONCLUSION

The Mn content of Co Mn microwires strongly affects the magnetic properties. While the Mn content is less than the critical value of about 6.5% the microwire shows easy axes in a plane perpendicular to its axis. The remagnetization of the microwires occurs by moment rotation, which provides a fast response to the applied external magnetic field. The proposed model of the dynamic magnetization process is in a good agreement with the experimental results. Microwires exhibit low values of eddy current loss factor and an extended frequency range where the real part of the permeability is near constant.

Frequency versus Lyapunov exponent map: A new approach to investigate dynamics of nonlinear magnetic systems

N. Y. Piskun^{a)} and P. E. Wigen

Department of Physics, The Ohio State University, Columbus, Ohio 43210

The complex Lyapunov exponent λ plays a vital role in characterizing the dynamics of a physical system. The real part of λ has frequently been related to as just the Lyapunov exponent and has been used for decades to characterize the stability of the system. The imaginary part or the frequency of oscillations can also give valid information about the dynamics of the system, particularly how it behaves near the equilibrium points. In this article we will show that the frequency versus Lyapunov exponent map can give additional information about the very nature of the system and provide background for detailed analysis concerning the applicability of the control technique and its robust nature. As an example of the applicability of the map, an appropriate model to investigate the origin and growth of the auto-oscillations are the circular YIG films. Starting with the low power ferromagnetic resonance spectrum and analyzing the behavior as a function of power the creation and evolution of "shoots" in the map have been demonstrated. The resulting map gives new insights about the relationship between the underlying dynamics of the system and the "growth" of the shoots into auto-oscillation fingers. This approach can explain many features of the auto-oscillation behavior and gives new insights into investigating techniques to control and synchronize chaos as well as to explain desynchronization bursts. © 1998 American Institute of Physics. [S0021-8979(98)51211-X]

INTRODUCTION

The field of controlling chaos has had a profound effect in different areas of science. The ability to eliminate chaotic behavior as well as the ability to "control" it can increase not only the ranges of stable regions but also can find new areas of applicability.¹ One of the main features of the chaotic system is sensitivity to initial conditions. A small perturbation to a system parameter can lead to large modifications of the behavior of the system. In this manner it is possible to influence the system behavior and obtain a desired periodic or "controlled" response from the system.

From the beginning of the chaos investigations the Lyapunov exponents were widely used to investigate the stability of the system around a position of equilibrium points or near stable or unstable manifolds. The ability to bring the system from the chaotic region to a stable region actually involves the ability to change the sign of the positive Lyapunov exponent λ . On the other hand, the imaginary part of the complex Lyapunov exponent or frequency describes the dynamic properties or the frequency of the oscillations around the equilibrium point.

Even though plots of the Lyapunov exponent and frequency versus system parameters can give some basic information about stability regions and system oscillations, they do not answer questions about the controlling techniques and the robustness of the controlled region. On the contrary, the frequency versus Lyapunov exponent map can provide im-

portant information about the "controlling" properties of the system that explains its behavior near the equilibrium points as well as provide background for detailed analysis concerning the applicability of the control technique and its robustness.

ORIGIN OF THE AUTO-OSCILLATIONS IN CIRCULAR THIN YIG FILMS

As an example of the applicability of the map, the model appropriate to investigate the origin and growth of the auto-oscillations in circular yttrium-iron-garnet (YIG) films at perpendicular resonance² has been used. In a small disk the boundary conditions introduce normal modes whose energies are shifted slightly above the bottom of the spin-wave band. The ferromagnetic resonance spectrum consists of a series of resonances with separations of typically 1 or 2 Oe. At higher powers, these modes exhibit nonlinear behavior leading to periodic and then chaotic auto-oscillations. It has been shown³ that in the case of thin circular YIG films the dynamics of the system can be approximated by the system of first-order nonlinear differential equations, representing the coupled magneto-static modes C_i :

$$\frac{dC_i}{dt} = -i\gamma \left[(H - H_i^{\text{res}} - i\Gamma_i) C_i + \left(\frac{h_p}{2} \right) I_i^* + 2\pi M_s \sum_{jkl} A_{ijkl} C_j^* C_k C_l \right], \quad (1)$$

where A_{ijkl} are the nonlinear coupling coefficients whose magnitudes are determined from the original Hamiltonian.

FIG. 1. (a) Plots of frequency (upper) and the Lyapunov exponent (lower) as a function of the magnetic field. The power was fixed at $ATT = -18$ a.u. and the magnetic field H was varied from 2 to 12 Oe. (b) The Lyapunov exponent vs the frequency map for the same sweep.

The constant characteristics of the system are M_s —the sample magnetization and I_i^* —the coupling with the rf field. H_i^{res} and Γ_i are the resonant field and half-width of the i th magneto-static mode and are taken directly from the low power FMR experiment. The variable parameters of the system are H —the magnetic field and h_p —the rf input power [expressed in attenuation (ATT) level units].

In the linear case the equations can be easily solved analytically giving the solution for each mode C in the form:

$$C = C_0 e^{\lambda t + i\omega t} - \frac{h_p I_i^*}{2(H - H_i^{\text{res}} - i\Gamma)}, \quad (2)$$

where $\lambda = -\gamma\Gamma$ and $\omega_\lambda = (H - H_i^{\text{res}})\gamma$.

As we can see, the Lyapunov exponent is negative and does not depend on the system variables H and h_p . The frequency depends linearly on the deviation of H from the resonant field position. The steady-state solution gives ordinary low-power FMR-type behavior. Despite its simplicity the linear approximation can serve as a starting point to future nonlinear investigation of Lyapunov exponents and frequencies.

In order to explore nonlinear properties of the system the equations were solved numerically to find corresponding Lyapunov exponents λ and frequencies ω as a function of the magnetic field H and power ATT for three magneto-static modes C_i . The plots of $\lambda(H)$ and $\omega(H)$ for small fixed power are shown on Fig. 1(a). Figure 1(b) is the single map of ω vs λ for the same H sweep. From Fig. 1, we can clearly observe that the increase in the Lyapunov exponent occurs when the frequencies of the magneto-static modes coincide or, in other words when the modes couple to each other. For the three-mode model we can obtain three possible couplings: (0,1) with (0,2) or (0,3) and (0,2) with (0,3). Two of them (0,1)–(0,2) and (0,2)–(0,3) are off-resonant couplings whereas (0,1)–(0,3) is a resonant coupling. The different position leads to different properties of couplings or “shoots” at high power resonance. The increase of power will only increase the magnitude of the Lyapunov exponent and only weakly affect the shape of “shoots.” This is particularly true for the first (0,1)–(0,2) shoot. To the contrary, the shape of a resonant shoot is strongly affected by the corresponding

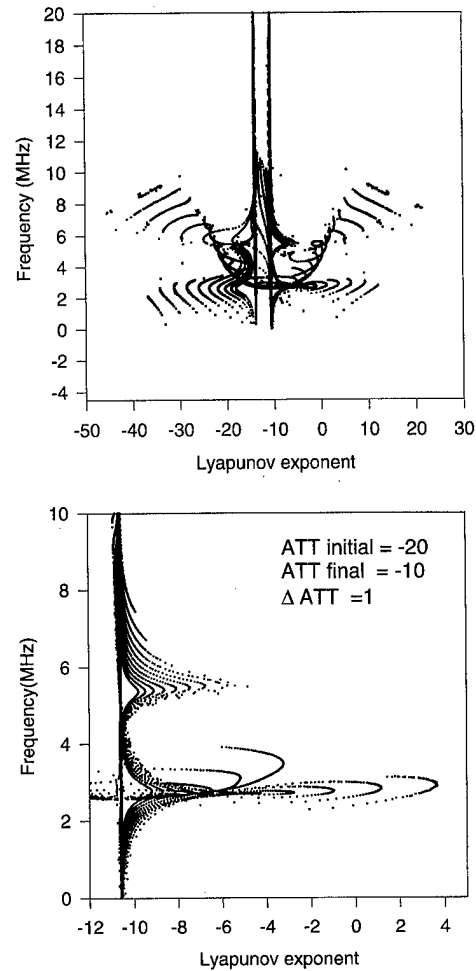

FIG. 2. (a) The Lyapunov exponent vs frequency map for 20 different H field sweeps. The power level has been varied from -20 to 0 a.u. in 1 a.u. steps. The first finger appears at a frequency of 2.5 MHz. The second finger is created by two colliding shoots at a frequency of 5.5 MHz. (b) The Lyapunov exponent vs the frequency map for 10 different H field sweeps. The power level has been varied from -20 to -10 a.u. in 1 a.u. steps.

FMR resonance. As can be seen from Figs. 2(a) and 2(b), as the power increases, it will shrink first at $ATT = -13$ [Fig. 2(b)] and then reappear again at $ATT = -10$.

When the Lyapunov exponent is equal to or greater than zero, the auto-oscillations start to be observed. This process is best seen from a global Lyapunov versus frequency map as presented on Fig. 2(b) where the magnetic field was swept through the resonance at 10 different attenuation levels. From this map the evolution of the mode coupling shoots into the auto-oscillation fingers can be observed. The first finger is obtained from the first nonresonant shoot as it crosses zero of the Lyapunov exponent. On the other hand, the analysis shows that the second finger is created by two colliding shoots: resonant (0,1)–(0,3) and nonresonant (0,2)–(0,3), which introduce additional complexities into the system.

STABILITY AND ROBUSTNESS ANALYSIS

In order to analyze the properties of our system a more extensive map is presented in Fig. 3 where the Lyapunov exponent is near zero. This map offers a unique opportunity

FIG. 3. The Lyapunov exponent vs the frequency map expanded in the region where the Lyapunov exponent is near zero.

to visualize and analyze the behavior of the system from the stability point of view. Figure 3 clearly shows that the lowest branch, which corresponds to the first auto-oscillation finger in the experiments, is very narrow in the frequency band and for small changes in the frequency during a given field sweep there is a large change in the Lyapunov exponent. It suggests that chaos can be suppressed very efficiently by applying a small periodic perturbation with a frequency near this value in an open loop control, or the chaotic state can be controlled relatively easily by driving the system into the

region of the map having a negative or zero Lyapunov exponent. Furthermore, the narrow frequency band might be related to the robust features of the system. In this case, we would expect it to be easier to bring the system into the controlled state but perhaps more difficult to maintain that control.

On the other hand, the analysis of the second finger, which was created by two colliding branches seems to give some promising insights. This branch has an increasing dependence of frequency on power and exhibits a much wider frequency band. As a result, it would be expected that it would be more difficult to establish a controlled state but once in that state the controlling process would be more robust.

The map also gives quantitative estimates for the auto-oscillation frequency for the first and the second finger. As shown on Fig. 3, the region of the map with positive Lyapunov exponent corresponds to the auto-oscillations. The experimental results at the onset of the auto-oscillations⁴ are in good agreement (within 10%) with the numerical estimations.

Coupling of reversal modes for an infinite ferromagnetic cylinder

Ching-Ray Chang^{a)}

Department of Physics, National Taiwan University, Taipei, Taiwan, Republic of China

Ching-Ming Lee

Division of Electrical Engineering, Chung Chou Junior College of Technology and Commerce, ChangHwa, Taiwan, Republic of China

We used amplitude equations to study the dynamic behavior of magnetization nucleation. Under certain conditions, the amplitudes of higher modes become dominant at large field and the reversal process moves to a new metastable state. Mode-mode coupling excites a cascade of nucleation modes and indicates that a common single-mode analysis is invalid. © 1998 American Institute of Physics. [S0021-8979(98)24511-7]

The magnetization reversal mechanism of a single-domain ferromagnetic particle has been studied for decades.¹⁻⁴ However, the experimental behavior of an isolated particle was only reported recently, and some of the data are inconsistent with the predictions of single-domain theory.^{5,6} An understanding of this problem is important from both fundamental interests and high-density data storage applications. According to the micromagnetics theory, the magnetization reverses through certain spatial modes when the external field reaches the nucleation field. Both the nucleation field and its corresponding mode can be obtained by solving the linearized Brown's equation.² However, it does not consider the possibility that an intermediate stable state may exist to trap the reversal process. Only a few attempts have studied the reversal process beyond the linear stability theory.^{4,7} Most of the theories are based on the assumption that a single mode is involved in the reversal process. However, there usually exist many intermediate metastable states during the reversal process and many different growing modes may arrive the same metastable state. Muller⁷ has also shown that in the case of a thick slab the state with finite deviation from saturation involves four different spatial modes. Therefore, conclusions based on the single-mode consideration are not sufficient and it is necessary to incorporate the equation of motion of magnetization to give a more satisfactory description on magnetization reversal.

We use a perturbative approach to investigate the dynamic behavior of the magnetization after nucleation in an infinite cylinder. Our studies can be briefly described as follows. The deviation of magnetization from its saturation state, i.e., the component perpendicular to the cylinder axis, is assumed to be a small quantity. In order to study the non-linear behavior, we keep the Landau-Lifshitz (L-L) equation to the third order of the deviation from the saturation. The deviated magnetization is separated as the spatial modes and time-dependent amplitudes. Using the spatial mode-expansion technique, we transform the partial differential L-L equation into a set of coupled ordinary differential

equations for the spatial mode amplitudes. By solving the amplitude equations we can then study the validity of the single-mode analysis.

For an infinite uniaxial ferromagnetic cylinder with radius R , $|\mathbf{M}(\mathbf{r})|$ is usually assumed to be conserved. Following the usual convention, the z axis is parallel to the cylinder axis and the external field is along its axis. Then \mathbf{m} can be written as $\mathbf{m}_0 + \mathbf{v}$, where \mathbf{m}_0 is the initially saturated state (0,0,1) and $\mathbf{v} = (v_x, v_y, \sqrt{1-v_x^2-v_y^2}-1)$ represents the deviation from the saturation state. Substituting \mathbf{m} into L-L equation and keeping terms up to third order of v_x and v_y , we have

$$\begin{aligned} \frac{\partial v_+}{\partial t} = & (\alpha - i\gamma) \left(\frac{2A}{M_s} \nabla^2 v_+ + H_+^{(1)} - H v_+ \right) + (\alpha - i\gamma) \\ & \times (H_+^{(2)} - H_z^{(1)} v_+) - (\alpha - i\gamma) v_+ \left[H_{\text{ex}}^{(2)} + H_K^{(2)} \right. \\ & \left. + H_z^{(2)} + \frac{1}{2} v_- \left(\frac{2A}{M_s} \nabla^2 v_+ + H_+^{(1)} \right) \right] \\ & - \frac{1}{2} \alpha v_+^2 \left(\frac{2A}{M_s} \nabla^2 v_- + H_-^{(1)} - H v_- \right), \end{aligned} \quad (1)$$

where γ is the gyromagnetic ratio and α is the damping parameter for dissipative effect, and $v_{\pm} = v_x \pm i v_y$,

$$H_{\text{ex}}^{(2)} = \frac{2A}{M_s} \nabla^2 \left(-\frac{1}{2} v_+ v_- \right), \quad H_K^{(2)} = \left(-\frac{1}{2} \frac{2K}{M_s} \right) v_+ v_-,$$

$H_{\pm}^{(1)} = H_x' \pm H_y'$. Further, $H_+^{(1)}$, $H_-^{(2)}$ are demagnetizing fields due to the magnetization $M_s(v_x, v_y, 0)$ and $M_s[0, 0, -\frac{1}{2}(v_x^2 + v_y^2)]$, respectively, and H is the sum of external field H_{ext} and $2K/M_s$.

It is natural to choose the solutions of the linearized Brown's equation,^{2,3} i.e., $\{\mathbf{v}_i(\mathbf{r})\}$, as our basis. Then we can write $v_+ = \sum_i C_i(t) v_{i+}(r)$, where C_i 's are the temporal amplitudes. With the same dimensionless units of Aharoni and Shtrikman,³ the first unstable mode for reduced cylinder radius $S \equiv R/(\sqrt{A/M_s}) \geq 1.1$ is the curling mode and this is the

^{a)}Electronic mail: crchang@phys.ntu.edu.tw

condition used in this article. In the z direction all eigenmodes have the form of $\cos(kz/R)$, and the eigenfield (normalized by $2\pi M_S$) for curling modes with different wave number k can be written as $h(k, S) = -1.08/S^2 - k^2/\pi S^2$. Hence the spectrum of eigenfield is continuous. The assumption of infinite length is a simplification for particles with negligible end effects.⁸ Thus we take the periodical boundary condition $v_+(z+2L) = v_+(z)$ for convenience, and $k_n = n\pi R/L$, $n \in N$. The value of L/R is interpreted as the aspect ratio of the particle. The first two curling modes $v_{1+}(\mathbf{r})$, $v_{2+}(\mathbf{r})$ can be written as $v_{1+}(\mathbf{r}) = N_1 i J_1(1.841r/R) e^{i\varphi}$, $v_{2+}(\mathbf{r}) = N_2 i J_1(1.841r/R) e^{i\varphi} \cos(\pi z/L)$, where J_1 is the first-kind Bessel function of order one and the normalization constants N_1 and N_2 satisfy the condition

$$\frac{1}{\pi R^2 2L} \int_{-L}^L dz \int_0^{2\pi} d\varphi \int_0^R dr r |v_{i+}(\mathbf{r})|^2 = 1.$$

Let $v_+ = \sum_i C_i(t) v_{i+}(\mathbf{r})$ in Eq. (1), we obtain the equations for the amplitudes C_i 's. The amplitude equations can be written as $\dot{C}_i = (\alpha - i\gamma)(H_i - H)C_i + N_i(C_i, C_j)$, where H_i is the eigenfield of mode i , and N_i represents the nonlinear mode-mode coupling. The linear instability (nucleation) occurs when external field H is equal to the largest eigenfield H_1 . To study the evolution of system after nucleation, we must solve the infinite coupled nonlinear equations. By the adiabatic elimination method,⁹ modes with large $|H_i - H|$ decay rapidly for the negative linear term $H_i - H < 0$ for $i \geq 2$ near the nucleation point. Therefore, a truncation is reasonable and we keep only the first few active modes (or "slow modes") to simplify the problem. The number of active modes depends on the periodicity L in z direction. For large L the eigenfields are very close for adjacent modes and hence the characteristic times are also of the same order of magnitude. We arbitrarily choose $p \equiv L/R = 10$ (to represent a needle particle with aspect ratio 10) and $S = 3$ (about 0.1 mm for $\gamma\text{-Fe}_2\text{O}_3$) in our calculations. To demonstrate the effect of mode-coupling we consider only the first two modes. In general C_i 's are complex amplitudes: pure imaginary amplitude C_i corresponds to the "flower state,"¹⁰ and pure real C_i represents the conventional curling mode (or the "vortex state,"¹⁰). Thus the amplitude equations contain four dynamic variables, but the number of variables can be further reduced for the imaginary parts of C_1 and C_2 are much smaller than their real parts.⁸ Therefore let X_1 and X_2 be the real part of C_1 and C_2 respectively, and the long-term behavior of the magnetization will be determined by:⁸

$$\dot{X}_1 = \frac{\alpha}{\gamma} \omega_0 \{ (h_1 - h)X_1 + AX_1^3 + BX_1X_2^2 \}, \quad (2)$$

$$\dot{X}_2 = \frac{\alpha}{\gamma} \omega_0 \{ (h_2 - h)X_2 + CX_2^3 + DX_1^2X_2 \}, \quad (3)$$

where $\omega_0 = 2\pi M_S \gamma$ and the coefficients are

$$A = 0.584(h_K + h - 2h_1) - \frac{0.393}{S^2},$$

FIG. 1. The bifurcation diagram of the amplitudes X_1 and X_2 of the two excited curling modes. The solid curve represents X_1 , and the dotted curve represents X_2 . For $|h| \in (0.12, 0.12075)$ only the first mode X_1 is excited, growing with increasing $|h|$; $X_2 = 0$. For $|h| \in (0.12075, 0.12155)$ X_2 grows with $|h|$, i.e., the second mode is excited; but X_1 decreases with $|h|$. As $|h| > 0.12155$ no stable stationary (X_1, X_2) exists.

$$B = 3 \left(0.584h_K - \frac{0.393}{S^2} \right) - 0.584(3h_2 + 2h_1 - 3h),$$

$$C = \frac{3}{2} 0.584(h_K + h - 3h_2) - \frac{1}{S^2} \left(0.5895 + \frac{1.168\pi}{p^2} \right),$$

$$D = 1.752(h_K + h - h_2 - 2h_1) - \frac{1.179}{S^2},$$

where $h_K = K/\pi M_S^2$. Time-independent solutions of (2) and (3) are: $(X_1=0, X_2=0)$, $(X_1 = \pm \sqrt{(h-h_1)/A}, X_2=0)$, $(X_1 = \pm \sqrt{-E/F}, X_2 = \pm \sqrt{(h-h_2+DE/F)/C})$, and $(X_1=0, X_2 = \pm \sqrt{(h-h_2)/C})$, here $E = h_1 - h - B(h_2 - h)/C$ and $F = A - BD/C$. The actual state of the magnetization depends on values of the parameters, especially on the effective anisotropic field h_K and the external field h .

For a positive or zero uniaxial anisotropy, i.e., $h_K \geq 0$, the only possible stationary solution is the saturation state, i.e., $(X_1=0, X_2=0)$. As the reverse external field h exceeds the nucleation field h_1 this solution becomes unstable. Any perturbative deviation from this state will grow without limit. Thus it seems that the magnetization reverses in a single step and it is consistent with earlier single-mode analysis.^{3,4} On the other hand, for negative h_K the magnetization can exhibit entirely different behavior. With a variation of the external field, the magnetization bifurcates from one solution to another. The bifurcation diagram is shown in Fig. 1 where we choose $h_K = -0.1$. The saturation state can only be stable for $|h| \leq |h_1| = 0.12$. For fields $|h| \in (0.12, 0.12075)$, nucleation takes place, and the saturation state is replaced by the stationary solution $(X_1 = \pm \sqrt{(h-h_1)/A}, X_2=0)$. After reduction to its normal form it can be easily shown that here occurs the supercritical pitchfork bifurcation.¹¹ From the figure we see that the amplitude of the curling mode grows with increasing $|h|$. Within this field range the single-mode approximation is valid because that the second curling mode with nontrivial z dependence is not excited. If the reverse

external field increases further above another threshold, $|h| \geq 0.12075$, then the previous single-mode solution becomes unstable and the $v_{2+}(\mathbf{r})$ is excited through the mode coupling. The stable solution changes to $(X_1 = \pm \sqrt{-E/F}, X_2 = \pm \sqrt{(h-h_2+DE/F)/C})$. Again the bifurcation is the supercritical pitchfork type. The second mode gradually becomes dominant with increasing $|h|$. For $|h| > 0.12155$, the solution of double-mode coupling also loses its stability and a perturbation of this mixed state grows without limit. Beyond this critical field the magnetization may transit to another stationary state involving more than two nucleation modes. The symmetry of the system lowers with increasing $|h|$. At the nucleation field $h=h_1$ the formation of the first curling mode removes the isotropy of magnetization. Continuous translation symmetry in z direction also breaks as the second curling mode is excited with further increasing $|h|$. We have also calculated the change of volume averaged z -component of the magnetization \bar{m}_z with $|h|$. Due to an increase of the amplitude X_1 of the first curling mode for $|h| \in (0.12, 0.12075)$, \bar{m}_z decreases as the applied field increases in this region. However, for $|h| \in (0.12075, 0.12155)$, because of the modulation factor $\cos[(\pi/L)z]$ in the second curling mode, \bar{m}_z will increase a little bit for the increasing amplitude of X_2 . Another stationary solution ($X_1=0$, $X_2 = \pm \sqrt{(h-h_2)/C}$) is always unstable to any perturbation in X_2 and thus it will not occur in reality.

We use the mode expansion and amplitude equations to analyze the response of magnetization deviated from saturation at nucleation. This study shows the reversal process of a single-domain particle can be much more complicated than that of the single-mode analysis predicated. Here only two cylindrical modes are considered and multimode analysis can be extended by including more modes to the amplitude equa-

tions. For an infinite ferromagnetic cylinder with positive or zero uniaxial anisotropy, we found that the curling mode grows without limit, with no other modes involved. In the case of negative anisotropy the stable stationary curling states exist even as the reverse external field exceeds the nucleation field. However, from the symmetry consideration, magnetization cannot only reverse with the curling modes of different axial periodicity discussed here.¹² Therefore, other kinds of modes, e.g., the buckling modes or the coherent mode should be excited by mode-mode coupling during the reversal. These noncylindrical modes should break the cylindrical symmetry as the deviation grows large. Our studies suggest that a cascade of nucleation modes occurs during the reversal process and the discrepancy between experimental data and single-domain theory can be attributed to the mode coupling.

Combining charge transfer with the Jahn-Teller electron-phonon coupling, the magnetic properties of LaMnO₃ and the influence of the Jahn-Teller effect are studied. The interaction parameters of super exchange coupling between manganese spins are obtained. In the ground state, manganese spins are antiferromagnetically ordered but canted by a small angle. The spectrum of the low-energy spin excitation is very close to that observed experimentally. Behaviors of magnetization and spin correlation functions of LaMnO₃ exhibit certain two-dimensional ferromagnetic characters, even though it is an A-type antiferromagnet with anisotropic super exchange coupling. These results agree with several experiments. Furthermore, it is expected that the super exchange interactions depend on the electron-phonon coupling strength exponentially, and the Néel temperature will exhibit isotope shift. © 1998 American Institute of Physics. [S0021-8979(98)39711-X]

The discovery of colossal magnetoresistance (CMR) in hole-doped perovskite manganese oxides R_{1-x}A_xMnO₃ (R = La, Pr, Nd, ... and A = Ca, Sr, Ba, Pb, ...) has renewed wide interest in these compounds. Properties of these compounds could qualitatively be explained within the framework of Zener's double exchange model,¹ in which the presence of the Mn³⁺ - Mn⁴⁺ mixed valence is responsible for both the ferromagnetic ordering and charge transport. Nevertheless, it is shown recently that, in addition to the double exchange interaction, the influence of the Jahn-Teller (JT) electron-phonon coupling is also important.^{2,3} Undoped LaMnO₃ exhibits distinct electronic and magnetic properties which relate to the magnetic and transport properties of hole-doped LaMnO₃. In order to fully understand the nature of CMR effect and related phenomena of doped manganese oxides, it is essential to clarify the magnetic properties and the influence of the JT effect in their parent compounds.

The electronic configuration of the LaMnO₃ is 3d⁴(t_{2g}³e_g¹), where three localized t_{2g} electrons form a core spin with S_c=3/2 while the one e_g electron is paralleled to the core spin due to strong Hund coupling J_H. With cubic symmetry, t_{2g} and e_g orbitals are threefold and twofold degenerate, respectively. Orbital degeneracy leads to a JT instability which causes the oxygen octahedra to distort, lowers its site symmetry to tetragonal and orthorhombic, and removes orbital degeneracy. In LaMnO₃, both t_{2g} and e_g orbitals hybridize with O 2p orbitals but the t_{2g} orbitals hybridize mainly with the 2p_π orbitals while the e_g orbital hybridizes mainly with the 2p_σ orbital. Therefore, the π-bonding orbitals t³-O:2p_π-t³ and σ-bonding orbitals e¹-O:2p_σ-e⁰ are formed.⁴ A virtual t³-p_π-t³=t²-p_π-t⁴ charge transfer and a real e¹-p_σ-e⁰ charge transfer

occur and cause super exchange interactions between manganese spins. With this picture in mind, we consider an effective JT electron-phonon mode together with the two kinds of charge transfer between Mn 3d and O 2p orbitals and write down the following Hamiltonian:

$$H = H_0 + H_{JT}, \quad (1)$$

$$H_0 = \sum_{i\alpha} \epsilon_d^\alpha d_{ie\alpha}^\dagger d_{ie\alpha} + \sum_{i\alpha} \epsilon_d^t d_{it\alpha}^\dagger d_{it\alpha} + \sum_{l\alpha} \epsilon_p p_{l\alpha}^\dagger p_{l\alpha} + \frac{U_\sigma}{2} \sum_{i\alpha} n_{ie\alpha} n_{ie\bar{\alpha}} + \frac{U_\pi}{2} \sum_{i\alpha} n_{it\alpha} n_{it\bar{\alpha}} - t^\sigma \times \sum_{\langle il \rangle \alpha} (d_{ie\alpha}^\dagger p_{l\alpha} + h.c.) - t^\pi \sum_{\langle il \rangle \alpha} (d_{it\alpha}^\dagger p_{l\alpha} + h.c.), \quad (2)$$

$$H_{JT} = \sqrt{\beta \hbar \omega} \sum_i n_i (b_i^\dagger + b_i) + \hbar \omega \sum_i \left(b_i^\dagger b_i + \frac{1}{2} \right). \quad (3)$$

Here d_{ieα}[†](d_{itα}[†]) and p_{lα}[†] are electron creation operators with spin α in the e_g(t_{2g}) orbital(s) on the ith Mn site and the p orbital on the lth O site, respectively. Their corresponding energy levels are ε_d^e, ε_d^t, and ε_p. The term t^σ(t^π) is the hopping matrix between 2p_σ(2p_π) and e_g(t_{2g}) orbitals. U_π and U_σ are electrostatic energies required to add an electron to a half-filled t_{2g} orbital and to an empty e_g orbital, respectively. The term n_i is the number operator of electrons on site R_i. β is the electron-phonon coupling constant and ħω is the phonon frequency. For LaMnO₃, these parameters are chosen as t^σ ≈ t^π ≈ 1.8 eV, U_π ≈ 7 eV, U_σ ≈ 4.5 eV, J_H ≈ 2.0 eV, ε_σ ≈ 4.5 eV, and ε_π ≈ 6.5 eV.⁵⁻⁷

FIG. 1. The electron-phonon coupling strength β dependence of super exchange coupling parameters J_0 (solid), J (diamond) and Néel temperature T_N (dash) for LaMnO_3 .

Making use of a canonical transformation, $\bar{H} = e^{-S} H e^S$ where $S = \sqrt{\beta/N\hbar\omega} \sum_i n_i (b_i - b_i^\dagger)$, we eliminate the linear term of phonon operators in Eq. (3). We then average \bar{H} over thermal equilibrium states of phonons and use Fröhlich's canonical transformation to remove operators $p_{l\alpha}$ and $p_{l\alpha}^\dagger$. Thus the effective transfer integral between the nearest neighbor Mn on the ab plane, t_{eff}^σ , and along the c axis, t_{eff}^π , are obtained,

$$t_{\text{eff}}^\sigma = (t^\sigma e^{-S_T})^2 / (\epsilon_\sigma + \beta), t_{\text{eff}}^\pi = (t^\pi e^{-S_T})^2 / (\epsilon_\pi + \beta), \quad (4)$$

where $\epsilon_\sigma = \epsilon_p - \epsilon_d^\sigma$ and $\epsilon_\pi = \epsilon_p - \epsilon_d^\pi$. $S_T = \sum_q |\lambda_q|^2 (\langle n_q \rangle + \frac{1}{2})$, $\lambda_q = \sqrt{\beta/N\hbar\omega} e^{iq \cdot r_i}$, and $n_q = 1/[\exp(\hbar\omega/k_B T) - 1]$. According to Goodenough's super exchange argument,⁵ the effective magnetic interactions can be obtained,

$$H_{\text{eff}} = -J_0 \sum_{\langle ii' \rangle} \mathbf{S}_i \cdot \mathbf{S}_{i'} - J \sum_{\langle ij \rangle} \mathbf{S}_i \cdot \mathbf{S}_j - D \sum_i (S_i^z)^2. \quad (5)$$

Here $J_0 = (t_{\text{eff}}^\sigma)^2 J_H / (8U_\sigma^2) (>0)$ and $J = -(t_{\text{eff}}^\pi)^2 / (8U_\pi) (<0)$ ⁵ are intralayer ferromagnetic interaction and interlayer antiferromagnetic interaction, respectively. $\langle ii' \rangle$ denotes the nearest neighbors within the layer and $\langle ij \rangle$ denotes the nearest neighbors between the two nearest layers. The third magnetic anisotropy term is introduced due to the anisotropic magnetic coupling of LaMnO_3 as mentioned above. The anisotropy constant $D \approx 0.15$ meV. Experimental results showed that LaMnO_3 is an A-type antiferromagnetic (AFM) insulator.⁸

Apparently, J_0 and J decrease with the increase of electron-phonon coupling strength β as shown in Fig. 1. Choosing $\beta = 0.105$ eV, which is within the range listed in the review article by Sturge,⁹ we obtain $J_0 \approx 0.748$ meV and $J \approx -0.53$ meV. These values are somewhat smaller than the experimental fitted values¹⁰ $J_0 \approx 0.83$ meV and $J \approx -0.58$ meV, but the ratio of J_0 to J is very close.

Applying a variational method to Eq. (5) in the semiclassical approximation of spin operators, it is found that spin cants a small angle to the c direction in the ground state. The angle between the spin moment and the c axis is about 86° . So the magnetic ground state is a canted structure and with a

FIG. 2. The reduced magnetization of GAFM (A), LaMnO_3 (B), Q2DFM (C) and A-type AFM without JT effect (F) are plotted as a function of the normalized temperature (T/T_N).

net moment ($\sim 0.13 \mu_B/\text{Mn}$) along the c axis, in agreement with the experimental data.¹¹ So the weak ferromagnetism is an intrinsic property of undoped LaMnO_3 .

The magnetic properties of LaMnO_3 can be studied by using the double-time Green's Function method. Within the random phase decoupling scheme, the spectrum of low-energy spin excitation is obtained,

$$E_{kk'} = \sqrt{A_k^2 - B_{k'}^2} \langle S^z \rangle, \quad (6)$$

$$A_k = 2J_0 z(1 - \gamma_k) - 2Jz' + 2D \quad B_{k'} = -2Jz' \gamma_{k'}, \quad (7)$$

where $\gamma_k = \cos(k_x a) \cos(k_y b)$, $\gamma_{k'} = \cos(k_z c)$; $z = 4$ and $z' = 2$ are coordinate numbers in the ab plane and along the c axis, respectively. At low temperature region, $\langle S^z \rangle \approx S$, the spin-wave spectrum agrees very well with experiment.¹² As can be seen from the energy spectrum, the magnetic interactions exhibit strong anisotropic dispersion.

In terms of the expression of sublattice magnetization for the case of $S = 2$,¹³ Néel temperature can be expressed as $T_N = S(S+1)/(3k_B C_1)$, where $C_1 = (2/N) \sum_{kk'} (A_k/E^2)$. It is found that T_N decreases with the increase of electron-phonon coupling strength β as shown in Fig. 1. For $\beta = 0.105$ eV, $T_N \approx 145$ K which is in good agreement with experimental data (140 K).^{11,12} The spin correlation functions $\langle S_j^- S_i^+ \rangle_{\parallel}$ in the ab plane and $\langle S_j^- S_i^+ \rangle_{\perp}$ along the c axis are also obtained,

$$\langle S_j^- S_i^+ \rangle_{\parallel} = \frac{2\langle S^z \rangle}{N} \sum_{k,k'} \left[\frac{A_k}{E} \coth \left(\frac{E_{kk'}}{2k_B T} \right) - 1 \right] e^{i\mathbf{K} \cdot (\mathbf{R}_i - \mathbf{R}_j)}, \quad (8)$$

$$\langle S_j^- S_i^+ \rangle_{\perp} = -\frac{2\langle S^z \rangle}{N} \sum_{k,k'} \left[\frac{B_{k'}}{E} \coth \left(\frac{E_{kk'}}{2k_B T} \right) \right] e^{i\mathbf{K}' \cdot (\mathbf{R}_i - \mathbf{R}_j)}, \quad (9)$$

where $E = \sqrt{A_k^2 - B_{k'}^2}$. Sublattice magnetization and correlation functions can be calculated self-consistently.

In Fig. 2, the reduced magnetization of LaMnO_3 is calculated and compared with those of quasi-two-dimensional ferromagnets (Q2DFM) and G-type antiferromagnets

FIG. 3. Wave-vector dependence of the transverse spin-spin correlation functions. The solid line and diamond represent the correlations of LaMnO_3 in $[100]$ and $[001]$ directions, respectively. The dashed line represents the correlation of GAFM in $[001]$ direction.

(GAFM) with the same parameters. A, B and C represent reduced magnetization curves of GAFM, LaMnO_3 and Q2DFM, respectively. The reduced magnetization of LaMnO_3 lies between those of Q2DFM and GAFM. It is obvious that LaMnO_3 exhibits a certain two-dimensional (2D) ferromagnetic character, which is in agreement with the experiment.¹² Furthermore, the reduced magnetization of A-type AFM without JT effect is also calculated (see the curve F in Fig. 2). The curves B and F are very close to each other, but the reduced magnetization of LaMnO_3 is smaller than that without JT effect at the same normalized temperature, which shows that the presence of JT effect weakens the magnetic coupling of the spins.

In Fig. 3, wave-vector dependence of the transverse spin-spin correlation functions of LaMnO_3 in the $[100]$ and $[001]$ directions are shown. In the $[100]$ direction, the transverse correlation decreases to zero with the increase of k_x in the first Brillouin zone (BZ), but in the $[001]$ direction, the transverse correlation increases when the wave vector k_z increases in the first BZ, while at $k_z = \pi/2$, the correlation is zero. The behavior of correlation of LaMnO_3 in the $[001]$ direction is different from that of GAFM which decreases with increasing of k_z as shown in Fig. 3. Due to the distinct ferromagnetic coupling in the ab plane and antiferromagnetic coupling along the c direction, the behavior of spin correlation exhibits anisotropy. The anisotropic super exchange coupling in the undoped LaMnO_3 may be the origin of anisotropic magnetoresistance recently discovered in the doped LaMnO_3 .¹⁴

According to Eq. (4), the magnetic coupling in LaMnO_3 depends on the JT phonon frequency which is proportional to $M^{-1/2}$, mass of the oxygen. Therefore isotope substitution of oxygen may affect the effective magnetic interactions between neighboring Mn cations, and the Néel temperature will exhibit isotope effect. From Eq. (4) and the formulas of J_0 , J and T_N , the isotope shift of Néel temperature in LaMnO_3 , denoted as $\Delta T = T_N^{16} - T_N^{18}$, can be calculated numerically. For LaMnO_3 , the phonon frequency $\hbar\omega \approx 0.05$ eV;¹⁵ thus the isotope shift of the Néel temperature is estimated to be $\Delta T \approx 17$ K. So the isotope substitution of heavy oxygen reduces the phonon frequency, and the Néel temperature by about 17 K. Therefore, the isotope shift of T_N should be able to be observed in further experiment.

In summary, the magnetic properties of LaMnO_3 and the influence of the JT effect on it are studied. It is found that in the ground state of LaMnO_3 , spins cant a small angle. The magnetization and the spin correlation functions show that LaMnO_3 possesses certain 2D ferromagnetic characters with anisotropic super exchange coupling. The JT effect substantially reduces the theoretical estimate of the Néel temperature, and the Néel temperature is expected to exhibit an isotope shift.

Application of spin-dynamics methods to a study of magnetization tunneling in many-spin systems

V. V. Dobrovitski and B. N. Harmon^{a)}

Ames Laboratory and Department of Physics and Astronomy, Iowa State University, Ames, Iowa 50011

Spin-dynamics methods were applied for the numerical study of magnetic tunneling in many-spin systems. A numerical technique based on the instanton approach was developed and the zero-temperature case as well as finite-temperature effects were considered. We show that even for a two-spin system results can differ considerably from those of a corresponding reduced one-spin (or collective spin) system. Moreover, it is argued that such a difference can take place for real materials such as magnetic molecules (e.g., Mn_{12}). Thus, consideration of the many-spin nature of some systems is shown to be important. © 1998 American Institute of Physics.

[S0021-8979(98)51311-4]

The phenomenon of magnetization tunneling is a fundamental property of mesoscopic magnetic systems. It has been studied for more than a decade and much progress has been achieved.¹ But most of the studies have been restricted by one important approximation: instead of systems where each spin is individually treated, reduced systems were considered, with the coupled separate spins forming a single collective degree of freedom. For example, tunneling in small ferromagnetic (FM) grains (as well as in molecular magnets such as Mn_{12}) was treated as tunneling of a single large spin representing the collective degree of freedom of all the small spins comprising the grain.¹ Analogously, the Néel vector is the corresponding collective degree of freedom in a small antiferromagnetic (AFM) particle.^{1,2} Such an approximation works well if the exchange interactions between spins are much stronger than the anisotropy energies governing the motion of the collective degree of freedom (collective spin). Thus the question arises, How strong does the exchange need to be to make the collective spin method valid and what can be expected if the ratio of exchange to anisotropy is not very large?

The primary goal of this article is to show that, even if exchange is considerably larger than anisotropy (say, five times larger), many-spin effects are important. We identify one of the parameters governing the tunneling rate in the many-spin case and give a qualitative explanation of its dependence on exchange and anisotropy constants. Our aim is to elucidate basic principles, so here we present results only for simple two-spin systems. For the same reason, we consider only systems with collinear ordering.

We use the instanton approach^{1,3} to describe the tunneling process quasiclassically. Thus, we consider systems consisting of several large spins (two spins for the cases presented below) where anisotropy is of the same order as the exchange coupling between the large spins. Our results can be applied qualitatively to such systems as assemblies of certain f ions (those possessing large spin on each ion) or Mn_{12} high-spin molecules, as described below.

We consider a system consisting of easy-axis spins

coupled by exchange interactions. The easy axis is chosen to be directed along the x axis. In general, if the total spin projection onto the easy axis is not zero, an additional easy-plane anisotropy should exist to allow tunneling.¹ Thus, introducing spherical angles θ and ϕ , the Hamiltonian of the system under consideration is

$$H = \sum_i K_i \sin^2 \theta_i \sin^2 \phi_i + \sum_i K'_i \cos^2 \theta_i + \sum_{i < j} J_{ij} [\cos \theta_i \cos \theta_j + \sin \theta_i \sin \theta_j \cos(\phi_i - \phi_j) \pm 1], \quad (1)$$

where K_i and K'_i ($K'_i \geq K_i$ for all i) are the easy-axis and easy-plane anisotropy constants, respectively, and J_{ij} are the exchange couplings. In third sum we add ± 1 (depending on the mutual direction of i th and j th spins) to provide normalization of the energy.

As we mentioned above, only systems with collinear ordering are considered, so the Hamiltonian (1) possesses two degenerate minima: $\theta_i = \pi/2$, $\phi_i = 0$ and $\theta_i = \pi/2$, $\phi_i = \pi$. These minima are separated by a potential barrier (the barrier height is governed by the easy-axis anisotropies K_i of all spins), and tunneling is possible between them. Within the instanton approach, we introduce imaginary time $\tau = it$ ($i = \sqrt{-1}$). Equations of motion for the system in imaginary time define the instanton trajectory, which starts at $\tau \rightarrow -\infty$ at the point corresponding to one minimum of the Hamiltonian (1) and ends at the other minimum at $\tau \rightarrow +\infty$. The value of imaginary-time action functional on the instanton trajectory \mathcal{S}_E defines the tunneling rate Γ :

$$\Gamma = \Gamma_0 \exp(-\mathcal{S}_E/\hbar), \quad (2)$$

where Γ_0 is the prefactor. The value of Γ is essentially determined by the instanton action \mathcal{S}_E (due to exponential dependence), so our analysis will be focused only on the quantity \mathcal{S}_E .

To solve the problem (both for zero- and finite-temperature cases) the following numerical scheme was used. We find the instanton as a solution of the boundary

^{a)}Electronic mail: harmon@ameslab.gov

value problem for a finite interval τ_0 of imaginary time; the boundary conditions are $\cos \theta_i = 0$ at both ends of the interval, $\tau = +\tau_0/2$ and $\tau = -\tau_0/2$. The quantity τ_0 is defined by the temperature: $2\tau_0 = \beta\hbar = \hbar/(k_B T)$, where k_B is Boltzmann's constant. The Newton quasilinearization method with step correction was used with an analytical initial approximation. If the analytical initial approximation is too far from the actual solution to attain convergence, a preliminary computation is performed, with another set of parameters chosen to attain convergence to the solution directly from analytical initial approximation. Then, results of this preliminary computation are used as an initial approximation for the calculation with the set of parameters we are interested in. Finally, integration of the Lagrangean along the instanton path gives the value of the action \mathcal{S}_E .

In calculations we use dimensionless energies normalized to some characteristic energy of the system E_0 and dimensionless imaginary time (using substitution $\tau \rightarrow E_0 \tau / \hbar$). Such a normalization does not change the value of the instanton action. Values of individual spins S_i are also normalized to some characteristic large spin S_0 ; in doing so the instanton action \mathcal{S}_E becomes S_0 times smaller.

To understand qualitatively the role of interaction between spins, let us analyze the Hamiltonian (1). Due to the lack of space it will be done briefly, omitting some details.

The easy-axis (first) term defines the potential barrier height and thus basically determines a general energy scale for the i th spin. The easy-plane (second) term permits the tunneling: both easy-axis and exchange terms conserve the projection of the total spin onto the easy axis. Thus, the rate of change of the projection of i th spin is governed by the quantity $K'_i - K_i$. The exchange (third) term transfers the rotation of i th spin to j th spin, so even if $K'_j - K_j$ is zero, the j th spin can tunnel: the i th spin (having nonzero $K'_i - K_i$) makes the j th spin rotate. The rate of rotation of j th spin in this case is governed by J_{ij} (if J_{ij} is small enough) or by $K'_i - K_i$ (if J_{ij} is strong, so that i th and j th spins rotate as a one collective spin).

The total energy of the system is conserved; since the energy at each minimum is zero, we obtain for the instanton action:

$$\mathcal{S}_E = - \int d\tau \sum_i S_i p_i \dot{\phi}_i, \quad (3)$$

where $p_i = i \cos \theta_i$ are canonical momenta conjugated to coordinates ϕ_i . It can be shown that \mathcal{S}_E is always positive in spite of the negative sign in (3).

Thus, the instanton action is defined by the rate of spin rotation. The exact solution for a single spin (see Ref. 1) predicts that the value \mathcal{S}_E is smaller when spins rotate faster. It holds also for the systems under consideration. Thus, rotation rate is one of the main parameters governing the instanton action. If the rotation rate of all spins is the same, there is no additional contribution from exchange term and the instanton action is the same as for noninteracting spins.

If spins rotate with different rates, exchange tends to unify rotation, i.e., push trajectories of individual spins closer to each other (for FM exchange) or pull them apart (for AFM exchange). Therefore, the exchange interaction

FIG. 1. Dependence of instanton action vs exchange for different values of the parameter K'_2 (governing the rotation rate of the second spin): (a) $K'_2 = 8$; (b) $K'_2 = 6$; (c) $K'_2 = 2.2$; (d) $K'_2 = 1.1$. All the other parameters are the same for all plots: $K_1 = K_2 = 1$, $S_1 = 1$, $S_2 = 3$, $K'_1 = 2$. Spins are FM coupled (exchange integral is negative).

slows down rotation of faster spins and accelerates rotation of slower spins. Thus, the contribution to the instanton action from faster spins increases and for slower spins it decreases. However, the contribution to the total action is larger for larger spins, so that accelerating the larger spins will increase the tunneling probability.

Following these guidelines, we can understand the curves shown in Fig. 1 for the system of two FM-coupled spins, $S_1 = 1$ and $S_2 = 3$. Dependences of instanton action versus coupling are presented there for different values of easy-plane anisotropy of the second spin K'_2 ; the other anisotropies are kept unchanged: $K_1 = K_2 = 1$, $K'_1 = 2$. When K'_2 is large [Fig. 1(a)], S_2 rotates faster, and exchange mainly accelerates the first spin, decreasing the instanton action. The contribution from slowing second spin is less, so the total action decreases with increased coupling. When we reduce K'_2 , rotation rates for both spins become equal, so exchange has almost no impact on instanton action [Fig. 1(b)]. Further reduction of K'_2 leads to a competition between acceleration of the second spin and slowing of the first one, so the peak appears [Fig. 1(c)]. For lower values of K'_2 , an increase in exchange leads predominantly to acceleration of the second spin, lowering the total action. These curves are quite characteristic for a rather large variation of parameters and the analysis remains qualitatively the same.

Nonzero temperature T can be accommodated quite naturally within the instanton approach using the theory developed by Affleck.⁴ In this case the tunneling rate is given by the same formula (2), but the instanton is the periodic trajectory with the finite period $2\tau_0$ (which is defined by the temperature, see above). With increasing temperature, the instanton action remains almost unchanged until some tem-

FIG. 2. Temperature behavior of instanton action for the two-spin model system of a Mn_{12} molecule. Results are shown for different sets of anisotropy constants: 1st set— $K_1=2$, $K'_1=2.2$, $K_2=K'_2=0$; 2nd set— $K_1=K'_1=0$, $K_2=2$, $K'_2=2.2$; 3rd set— $K_1=K_2=1$, $K'_1=K'_2=1.1$. Spin values are $S_1=1$, $S_2=3$. Spins are AFM coupled, and the coupling strength is $J=10$. The plot for the single spin $S=2$ is also shown; anisotropies are $K=2$ and $K'=2.2$. Note that this single spin is “equivalent” to all parameter sets of two-spin system presented here.

perature region, called the crossover region, is reached. At the crossover region the instanton action starts to decrease; it means that the thermal effects, instead of tunneling, govern the relaxation rate.

The present study can serve as a qualitative model of the extensively investigated molecular magnet Mn_{12} . We consider a Mn_{12} molecule as consisting of two AFM-coupled spins, $S_1=6$ and $S_2=16$. Individual anisotropies for these spins are not known, but the equivalent single spin is known⁵ to have the value $S=10$ and the easy-axis anisotropy equivalent to about 60 K. We assume that the tunneling in Mn_{12} is provided by a small easy-plane anisotropy, $|K'-K|\ll K$.⁶ The value of coupling J can be estimated to be about 300 K.

Thus, we consider the model system consisting of two AFM-coupled spins $S_1=1$ and $S_2=3$ ($1:3\approx 6:16$). Energy is normalized to have $K=2$, so individual easy-axis anisotropies obey $K_1+K_2=2$. Normalized coupling J is 10. Below we present results for $K'=2.2$ (so individual easy-plane anisotropies obey $K'_1+K'_2=2.2$); calculations for the values down to $K'=2.02$ give qualitatively the same results.

Results of computations for such a model system are shown in Fig. 2. Temperature dependencies of instanton action are shown for different easy-axis and easy-plane anisotropies. Normalized temperature is used: $T(\text{K})=12\text{ K}\times T(\text{dimensionless})$. The ideas described above can be used to understand these curves: to get larger instanton action we

slow down the larger spin by making the easy-plane anisotropy of this spin equal to zero (along with the easy-axis anisotropy, since $K_i\leq K'_i$). A zero anisotropy of the smaller spin gives smaller instanton action (we increase K'_2 up to the limiting value 2.2 thus accelerating S_2 as much as possible). It is easy to see that instanton action varies considerably, and can be 20% higher than that of “equivalent” single spin (the lowest curve in Fig. 2). If we estimate the difference in relaxation times (using $S_0\approx 6$), we find that the relaxation rate is about 2000 times smaller for the two-spin system in comparison with the “equivalent” single-spin system. This result could offer an alternative explanation for the unusually small value of the pre-exponential factor⁷ observed for Mn_{12} . The crossover temperature for the two-spin system also decreases considerably and achieves a value almost two times less than that for the “equivalent” single spin. Thus, even if exchange is five times larger than anisotropy, many-spin effects are important for determining the crossover temperature.

In summary, for two-spin systems with collinear ordering we demonstrated that many-spin effects are important even if exchange is considerably larger than anisotropy. We have shown that qualitative understanding of our results can be achieved by analysis of the spin rotation rates which are governed by easy-plane terms in the Hamiltonian. Finite-temperature effects were also studied for the two-spin model of the magnetic molecule Mn_{12} . We demonstrated that in this case the temperature dependence of the tunneling probability for the two-spin system can differ considerably from the corresponding collective spin system.

The authors report on NMR and susceptibility measurements in $\text{Sr}_{14-x}\text{Na}_x\text{Cu}_{24}\text{O}_{41}$ for $0 \leq x \leq 2$. The analysis of the susceptibility evidences that only a small fraction of Cu^{2+} spins are involved in the dimerization of $\text{Cu}(1)\text{O}_2$ chains. The introduction of extra holes by Na^+ doping is found to decrease the $\text{Cu}(1)^{2+}$ uniform static susceptibility without affecting the amplitude of the dimerization gap. On the other hand, the amplitude of the spin gap in the $\text{Cu}(2)_2\text{O}_3$ two-leg-ladders and the resistivity are reduced by doping. The origin of the discrepancy in the amplitude of the gap estimated by means of nuclear spin-lattice relaxation and susceptibility measurements is briefly discussed. © 1998 American Institute of Physics. I. INTRODUCTION

The discovery of high-temperature superconductivity has brought renewed interest in the study of low-dimensional cuprates,¹ and the search for superconductivity in the quasi-one-dimensional (quasi-1D) ones [$(\text{Sr}, \text{Ca})_{14}\text{Cu}_{24}\text{O}_{41}$] has recently been proven to be successful.² This fact is of major interest and could lead to a reexamination of the properties of high- T_c superconductors (HT_cSC) in the frame of a quasi-1D scenario, particularly if a phase separation takes place.³ Therefore an extensive investigation of either pure or hole doped quasi-1D cuprates and a comparison with the normal-state properties of HT_cSC is required. $\text{Sr}_{14}\text{Cu}_{24}\text{O}_{41}$ is the parent of this new family of quasi-1D superconductors and its structure comprises $\text{Cu}(1)\text{O}_2$ chains and $\text{Cu}(2)_2\text{O}_3$ 2-leg-ladders.⁴ $\text{Cu}(1)^{2+}$ spins dimerize around 80–100 K and the origin of this dimerization is still under debate.⁵ On the other hand, the comprehension of the properties of spin excitations in the 2-leg-ladders could be considered almost complete if the discrepancy in the value of the gap derived from DC susceptibility and NMR measurements is not concerned.¹² The chains are intrinsically doped by six holes due to the three excess O^{2-} ions present in the stoichiometry. By a substitution of Sr^{2+} with Ca^{2+} , an increase in the chemical pressure is obtained, a more efficient transfer of holes to the ladders is achieved, and a superconducting state is realized.² In this paper we report on the modifications of the spin dynamics in the chains and in the 2-leg-ladders of $\text{Sr}_{14}\text{Cu}_{24}\text{O}_{41}$ after an introduction of extra holes by substituting Sr^{2+} with Na^+ . By varying the Na^+ content we expect to vary the hole concentration in the ladders due both to an increase of the chemical pressure and to the heterovalent nature of the substitution.

II. RESULTS AND DISCUSSION

For all samples the resistivity was observed to increase on cooling and two different activated regimes, with energy

barriers decreasing with doping (see Fig. 3 later on), were evidenced. The two regimes are separated by a crossover temperature $T_p \approx 130$ K where an anomaly, possibly related to structural distortions,⁶ is observed. These distortions could be relevant to the dimerization of $\text{Cu}(1)\text{O}_2$ chains since they modify the $\text{Cu}(1)\text{--O--Cu}(1)$ bonding angle and the corresponding superexchange coupling.⁷

The temperature dependence of the susceptibility is dominantly contributed from $\text{Cu}(1)^{2+}$ spins and is similar to the one expected for the case of spin dimerization with an activation energy around 140 K as explained below.⁵ $\text{Cu}(2)^{2+}$ spins in the ladder are strongly coupled by forming a spin singlet state and their contribution is rather small, although not negligible for $T \geq 200$ K. The total spin susceptibility is $\chi = (10/24)\chi_D + (14/24)\chi_L$, with χ_D the susceptibility of the dimerized $\text{Cu}(1)\text{O}_2$ chains and χ_L that of the ladder. The coefficient in front of each term gives the relative occupation of $\text{Cu}(1)^{2+}$ and $\text{Cu}(2)^{2+}$ spins per formula unit. $\chi_{D,L}$ can be written in the form

$$\chi_{D,L} = \frac{N_A g^2 \mu_B^2}{k_B T} \frac{z_{D,L}(T, \Delta_{D,L})}{1 + 3z_{D,L}(T, \Delta_{D,L})}. \quad (1)$$

For a chain of noninteracting dimers⁸ one has $z_D = \exp(-\Delta_D/T)$, while for a 2-leg-ladder in the isotropic limit ($J_{\parallel} = J_{\perp} = J = 2\Delta_L$, J_{\parallel} being the superexchange coupling along the chains and J_{\perp} in the rungs) and for $J \gg T$, one has $z_L \approx 0.4 \sqrt{T/2\Delta_L} \exp(-\Delta_L/T)$.⁹ From a quantitative analysis of the susceptibility data at low temperatures ($T \leq 200$ K), it turned out that only 35% of $\text{Cu}(1)^{2+}$ spins per formula unit contributes to the susceptibility. As first suggested by Carter *et al.*¹⁰ this reduction should be associated to the possible formation of Zhang–Rice (ZR)¹¹ singlets between the extra-holes intrinsically present in this compound and the $\text{Cu}(1)^{2+}$ spins in the chains. If one considers that there are n_h of these

FIG. 1. Temperature dependence of the DC susceptibility for the $x=0$ (squares) and $x=2$ (triangles) samples. A low-temperature Curie-Weiss contribution $\chi_{CW} = C/(T - \Theta)$ has been subtracted from the raw data, with $C(x=0) = 0.015$ emu K/mol Cu^{2+} , $C(x=0.02) = 0.0167$ emu K/mol Cu^{2+} , $\Theta(x=0) = -1.23$ K and $\Theta(x=0.02) = -1.14$ K. The solid lines give the best fit according to Eqs. (1) and (2) over all the temperature range.

localized holes in the chain, per formula unit, the DC susceptibility should be reduced by a factor $(10 - n_h)/10$. Then one has

$$\chi = \frac{10 - n_h}{24} \chi_D + \frac{14}{24} \chi_L. \quad (2)$$

By fitting the low-temperature (for $T < 130$ K χ_L is negligible) data with just the first term of Eq. (2) one can derive n_h and Δ_D . One finds $\Delta_D \approx 140$ K and weakly sample dependent, while the number of localized holes in the chain increases from $n_h \approx 6.4$ to $n_h \approx 7$ on increasing x . Keeping these two parameters fixed one can estimate Δ_L from the fit of the data over all the temperature range with Eqs. (1) and (2) (see Fig. 1). One finds $\Delta_L \approx 500$ K for $x=0$, while $\Delta_L \approx 420$ K for $x=2$. The value for n_h derived for the pure compound is in good agreement with the value $n_h = 6$ that one would expect on the basis of considerations on the oxygen stoichiometry. From the same considerations, for $x=2$ one would expect a stronger increase of n_h . The fact that only a slight increase is observed suggests that part of the holes start to be doped into the $\text{Cu}(2)_2\text{O}_3$ ladders, causing the observed decrease in Δ_L .

Now we turn to the discussion of the NMR measurements. The temperature dependence of ^{23}Na $1/T_1$ for $H \parallel b$ is shown in Fig. 2(b). One observes an increase on decreasing temperature and then a sharp activated decrease at low temperatures. The low-temperature dependence is characterized by an activation energy $\Delta_D \approx 130$ K, very close to the one derived from susceptibility measurements, implying that ^{23}Na nuclei below ~ 130 K probe essentially $\text{Cu}(1)^{2+}$ spin dynamics. Only at high temperatures the contribution from $\text{Cu}(2)^{2+}$ spin fluctuations to the relaxation can be observed, causing a smooth increase in ^{23}Na $1/T_1$. On the other hand,

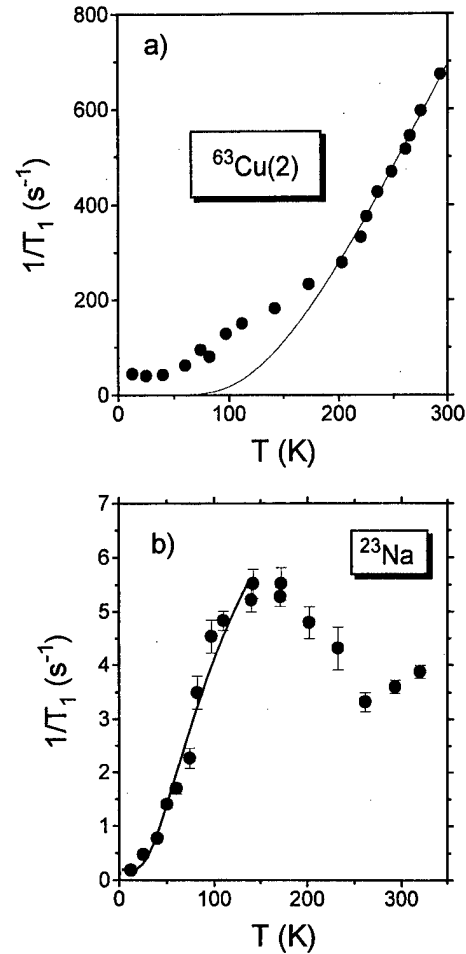

FIG. 2. (a) Temperature dependence of $^{63}\text{Cu}(2)$ $1/T_1$ for the $x=2$ oriented powder sample in the magnetic field $H = 5.9$ T along the b axis. The solid line describes the high-temperature activated behavior. (b) Temperature dependence of ^{23}Na $1/T_1$ for the same sample in a magnetic field $H = 5.9$ T along the b axis. The solid line shows the activated behavior for $\Delta_D = 130$ K.

this is the dominant contribution to $^{63}\text{Cu}(2)$ relaxation at high temperatures, where an activated trend [see Fig. 2(a)], characterized by activation energies decreasing with doping from around 650 to ≈ 500 K, is observed. We remark that these values are higher by a factor ~ 1.4 than the ones derived from DC susceptibility measurements, a situation similar to the one found in other 2-leg-ladders,¹² but not in all of them.¹³ Around 90 K a bump in $^{63}\text{Cu}(2)$ $1/T_1$ superimposed to the activated behavior is obviously seen. This extra contribution is strongly field dependent and possibly related to the slowing down of the fluctuations associated to the diffusive motions of the holes.¹⁴

In $S = 1/2$ 2-leg-ladders and dimerized chains, at low temperatures and low magnetic fields ($g\mu_B H/k_B \ll T \ll \Delta_{D,L}$), only the low part of the triplet magnon branch is occupied. Then¹⁵ the nuclear relaxation is driven by indirect $q \approx 0$ processes involving triplet excitations, its temperature dependence is related to the population of these excitations and one finds that $1/T_1 \propto \exp(-\Delta/T)$. For $T \gg \Delta_{D,L}$ $1/T_1$ reaches asymptotically a constant value related to Heisenberg exchange frequency. This is indeed the behavior observed for $^{63}\text{Cu}(2)$ in the $S = 1/2$ AF 2-leg-ladder⁷ and in S

FIG. 3. Doping dependence of the high-temperature transport activation energy E_a (solid squares), Δ_L derived from $^{63}\text{Cu}(2)$ $1/T_1$ (solid circles), Δ_L derived from DC susceptibility measurements (solid triangles), Δ_D estimated from ^{23}Na $1/T_1$ (open circles), and Δ_D from DC susceptibility measurements (open triangles). The lines are guides to the eye.

$S=1/2$ dimerized chains,¹⁶ however, it is not the one observed for ^{23}Na $1/T_1$ in $\text{Sr}_{14-x}\text{Na}_x\text{Cu}_{24}\text{O}_{41}$ which between these two regimes shows a broad maximum. The origin of this maximum is still unclear and a systematic study of the field dependence of ^{23}Na $1/T_1$ is required to understand whether it has a dynamical origin or if it is due to a modification in the hyperfine coupling constants on cooling, related to the occurrence of lattice distortions.

III. SUMMARIZING REMARKS AND CONCLUSIONS

We have presented a series of NMR and susceptibility measurements aiming at clarifying the modifications of the spin dynamics in $\text{Cu}(1)\text{O}_2$ chains and in $\text{Cu}(2)_2\text{O}_3$ ladders as a function of temperature and doping. The magnetic properties in the chains are essentially the ones expected for weakly interacting dimers. In fact, the analysis of the susceptibility supports the presence of a rather small number of spins which dimerize while the other $\text{Cu}(1)^{2+}$ spins form ZR singlets with localized holes. The presence of this isolated dimers separated by ZR singlets could also explain the presence of neutron scattering peaks at wave vectors around $1/4$ – $1/6$ reciprocal lattice units.¹⁷ The amplitude of the dimerization gap was estimated $\Delta_D \approx 140$ K either from DC susceptibility or ^{23}Na $1/T_1$ data and was found not to vary with doping (see Fig. 3), suggesting that the dimers are weakly interacting, thus supporting our analysis of the DC susceptibility. The structural distortions evidenced in NQR spectra⁷ and resistivity measurements are believed to modify the superexchange coupling along the chains.

As for the $\text{Cu}(2)_2\text{O}_3$ 2-leg-ladders we observe that the amplitude of the gap Δ_L , derived both from DC susceptibility and $1/T_1$ measurements decreases with increasing doping

(Fig. 3). This behavior is analogous to that of the activation barrier E_a measured through resistivity (Fig. 3) and evidences a frustration of the AF correlations on increasing the hole itineracy, analogous to the one observed in underdoped HTcSC. It is interesting to point out that the initial suppression rate for the gap $s = -d\Delta_L/dx$ is higher for Na-doped ($s \approx 70$ K/ Na^+ ion) than for Ca-doped samples ($s \approx 45$ K/ Ca^{2+} ion),^{18,19} as expected for the heterovalent nature of the Sr^{2+} for Na^+ substitution. On the other hand, we remark that the amplitude of the gap derived from $1/T_1$ and DC susceptibility differs by a factor ~ 1.4 . Sachdev and Damle,²⁰ on the basis of a semiclassical model for the spin excitations in quasi-1D systems with a gap, which should be valid for $T \ll \Delta$, found that the gaps probed by $1/T_1$ and χ differ by a factor of 1.5, very close to what is experimentally measured. However, one should notice that in other quasi-1D gapped quantum antiferromagnets (dimerized chains or in other ladder compounds with $J_\perp > J_\parallel$), where this model should still apply, the gap derived from susceptibility and $1/T_1$ is the same. A possible origin of the discrepancy is that excitations around $q \approx \pi$, involving 3-magnons,¹⁵ can become more important for $J_\parallel > J_\perp$. In that case the continuum of spin excitations moves to lower energies and there is a higher density of states with energies $2\Delta_L$ which are involved in the 3-magnon processes. Then one should have an extra contribution of the form $(1/T_1)_{(3)} \propto \exp(-2\Delta_L/T)$. An agreement with the susceptibility measurements can be found in this case provided the amplitude of 3-magnon terms is six times larger than that of 2-magnon processes. The fact that the disagreement in the estimate of Δ_L is absent for $J_\perp > J_\parallel$ suggests that the origin of the discrepancy is inherent to the form of the magnon dispersion curve.

Magnetic properties and spin dynamics in hole-doped $S=1$ AF chain: ^{89}Y NMR and susceptibility in $\text{Y}_{2-x}\text{Ca}_x\text{BaNiO}_5$

F. Tedoldi, A. Rigamonti, C. Brugna, and M. Corti^{a)}

INFN-Department of Physics "A. Volta", University of Pavia, I-27100 Pavia, Italy

A. Lascialfari

Department of Chemistry, University of Firenze, I-50144 Firenze, Italy

D. Capsoni and V. Massarotti

Department of Physical Chemistry, University of Pavia, I-27100 Pavia, Italy

Hole-doping effects in Haldane chain have been studied by means of magnetic susceptibility and ^{89}Y nuclear magnetic resonance in $\text{Y}_{2-x}\text{Ca}_x\text{BaNiO}_5$ for $x=0$, $x=0.06$ and $x=0.18$. In nominally pure YBNO detailed information on this prototype of Haldane systems is extracted. In the charge-doped compounds the ^{89}Y relaxation rates indicate that holes induce low-energy excitations with an effective spectral density having a structure characterized by a narrow central peak.

© 1998 American Institute of Physics. [S0021-8979(98)24611-1]

I. INTRODUCTION

The compound Y_2BaNiO_5 (YBNO) is characterized by the presence of weakly coupled chains of strongly interacting Ni^{2+} ($S=1$) ions.¹ The ratio of interchain/intrachain coupling ($|J'/J| \leq 5 \times 10^{-4}$,^{2,3} indicates that YBNO can be considered a good realization of $S=1$ one-dimensional Heisenberg antiferromagnet (1D-HAF). The magnetic properties of YBNO are well described by the Hamiltonian

$$H = J \sum_i S_i \cdot S_{i+1} + D \sum_i (S_i^z)^2 + E \sum_i [(S_i^x)^2 - (S_i^y)^2] \quad (1)$$

with $J \approx 285$ K, $D \approx -8$ K, and $E \approx 3$ K.^{2,3}

YBNO has triggered a great deal of interest, since the relatively high gap ($\Delta \approx 100$ K) and the small values of the anisotropy terms D and E allow one to study the Haldane⁴ ground state in a wide temperature range. Furthermore, the heterovalent substitutions of Ca^{2+} for Y^{3+} introduce holes mainly residing in the Ni-O chains⁵ and induce relevant modifications in the magnetic properties of this prototype of 1D-HAF. The possible itinerancy of the holes can induce novel features in the spin liquid state, with low-energy excitations lying into the gap.^{5,6}

Here we present magnetic susceptibility χ , ^{89}Y shift K , T_1 , and T_2 measurements in $\text{Y}_{2-x}\text{Ca}_x\text{BaNiO}_5$.

II. EXPERIMENTALS AND EXPERIMENTAL RESULTS

Solid state reaction has been used to obtain $\text{Y}_{2-x}\text{Ca}_x\text{BaNiO}_5$ in the compositions: $x=0$, $x=0.06$, $x=0.18$. X-ray diffraction indicated a single-phase compound and was used also to estimate the real amount of doping. The susceptibility measurements have been performed by SQUID magnetometer, in field cooled and zero field cooled conditions. No appreciable difference between the two cases have been detected, in the temperature range 3–250 K. The mag-

netization curves appear linear, in all samples, up to $H_0 = 0.5$ T. The experimental data of $\chi = M/H_0$ are reported in Fig. 1 after subtraction of a core-diamagnetic term $\chi_d = 1.28 \times 10^{-4}$ emu/mole.

Standard pulse NMR techniques have been used to obtain ^{89}Y spectra and relaxation times in external magnetic fields $H_0 = 5.9$ T and $H_0 = 9.4$ T. In pure YBNO, as already noticed,⁷ the spectrum results from the powder distribution of an hyperfine field h of cylindrical symmetry. Due to the orthorhombic symmetry at the Yttrium site, this cylindrical symmetry has to be related to a compensation with the anisotropy in the single ion susceptibility.⁸ A shift parameter $K = \frac{1}{3}K_{\parallel} + \frac{2}{3}K_{\perp}$ can then be defined (\parallel and \perp to the x -chain axis). The powder distribution of the dipolar part of h is responsible of the structure of the NMR line, centered at the frequency $\nu = \gamma H_0(1 + K)$. In $\text{Y}_{2-x}\text{Ca}_x\text{BaNiO}_5$ the homogeneous broadening of the line prevents the same type of analysis of the spectra. Then K has been obtained from the

FIG. 1. Magnetic susceptibility χ in $\text{Y}_{2-x}\text{Ca}_x\text{BaNiO}_5$ as a function of temperature. In the inset the behavior of χ in pure YBNO after subtraction of the Curie-Weiss term is shown. The solid line is the best fit of the data according to Eq. (2) in the temperature range $T \leq 100$ K, where it is expected to hold.

^{a)}Electronic mail: CORTI@PV.INFN.IT

FIG. 2. Shift K of the ^{89}Y NMR line (with respect to a solution of YCl_3) in pure YBNO, for two values of the external magnetic field H_0 [part (a)]. In part (b) the shift for the Ca-doped compounds are reported (no field dependence was noted). The solid lines are the best fit behaviors, for $T \leq 150$ K, according to the function $K(T) = K(0) + (B/\sqrt{T})e^{-\Delta_K/T}$. The lack of experimental data for $30 \text{ K} \leq T \leq 80 \text{ K}$ in (b) corresponds to the disappearing of the echo signal due to the divergence in T_2^{-1} .

position of the maximum in the resonance peak ($\approx K_{\perp}$). In Fig. 2 the temperature behaviors of K are reported, for different values of the external field, in pure and doped YBNO.

The recovery of the nuclear ^{89}Y magnetization $M_z(t)$ in the doped compounds has a stretched-exponential form, particularly at low temperatures ($T \leq 250$ K). Therefore all the recovery plots have been fitted by the law $M_z(t) = M_z(0)\exp[-(t/T_1)^\beta]$ (see Fig. 3).

The decay of the ^{89}Y echo signal has a gaussian behavior, for $T \geq 250$ K. Instead, in the latter case and for $T \leq 150$ K, the decay of the echo turns to an exponential form, with a tendency to become stretched. In Fig. 4 the values of the spin decay rates are reported.

FIG. 3. ^{89}Y spin-lattice relaxation rates as a function of temperature in $\text{Y}_{2-x}\text{Ca}_x\text{BaNiO}_5$. The values of β in the stretched exponential are $\beta \approx 1$ for $x=0$, while in the doped compounds β is close to 1 in the high temperature range and becomes $\beta \approx 0.8$ for $T < 200$ K. In the inset the semilogarithmic plot of T_1^{-1} as a function of $1000/T$ is shown. The dotted lines are the best fit of the data according to a gapped behavior, with $\Delta_{T_1} = 250$ K. The solid line is the best fit according to the model discussed in the text for the extracontribution due to Ca doping.

FIG. 4. ^{89}Y spin-spin relaxation rates in $\text{Y}_{2-x}\text{Ca}_x\text{BaNiO}_5$. The dotted line represents the theoretical behavior for T_2^{-1} derived from the single-Lorentzian spectral density of the excitations which describes the doping-related extracontribution to T_1^{-1} (see Fig. 3).

III. ANALYSIS OF THE RESULTS AND CONCLUSIONS

The behavior of χ in nominally pure YBNO is typical of $S=1$ HAFs containing a small percent of magnetic impurities, most likely are due to oxygen nonstoichiometry.⁸ One can try to account for the experimental results, for $T < 100$ K, by means of the expression^{9,10}

$$\chi(T) = \chi(0) + \frac{C}{T - \Theta} + \frac{A(\Delta_\chi)}{\sqrt{T}} e^{-\Delta_\chi/T}. \quad (2)$$

$\chi(0)$ takes into account the possible orbital contribution (Van Vleck paramagnetism) and/or the one related to the anisotropy in the magnetic Hamiltonian.^{9,11} Furthermore, in Eq. (2) we have added a Curie-Weiss term to describe the effects of paramagnetic impurities, dominant at low temperatures ($T < 20$ K). By fitting the data (Fig. 1) with Eq. (2), one derive $\chi(0) = 4.5 \times 10^{-4}$ emu/mole, $C = 1.56 \times 10^{-2}$ emu K/mole, $\Theta = 0.5$ K, $A = 1.2 \times 10^{-2}$ emu K/mole, and $\Delta_\chi = 92$ K. From the value of C , for $s=1/2$ defects (as it is the case either for O^- or Ni^{3+} in the low-spin state) one can estimate a concentration of 3×10^{-2} impurities for Ni ion.

After subtraction of the Curie contribution (inset in Fig. 1), $\chi(T)$ shows the behavior described by the third term in Eq. (2). The value of Δ_χ is not far from the separation between the singlet ground state and the first excited magnetic state, obtained by neutron scattering $\Delta_{\text{NS}} = 102$ K.^{2,3} It should be noted that Δ_χ , as well as Δ_{NS} , are smaller than the gap theoretically expected ($\Delta_{\text{Th}} \approx 117$ K) if one uses $J = 285$ K (Ref. 12) and sets $\Delta_{\text{Th}} \approx 0.4105$ J, as suggested by numerical techniques^{9,10} for Heisenberg Hamiltonian [$D=E=0$ in Eq. (1)]. On the other hand, the presence of easy-axis anisotropy (namely, $D < 0$) increases the energy separation between the ground state and the first excited magnetic state. If one assumes for the prefactor A in the third term of Eq. (2) the expression derived in the free boson approach,⁹ i.e., $A_{\text{Th}} = 2(g\mu_B)^2/\nu\sqrt{2\pi}$ and a spin wave velocity $v = 2.49$ J, then $A_{\text{Th}} \approx 1.8 \times 10^{-2}$ emu $\sqrt{\text{K}}$ /mole, again larger than the experimental result.

TABLE I. Curie constants and temperatures extracted from the best fit of the data in Fig. 1. n is the number of magnetic impurities for Ni ion deduced from C.

x	C (emu K/mole)	θ (K)	n
0	1.56×10^{-2}	-0.5	3×10^{-2}
0.06	1×10^{-1}	-6.5	2×10^{-1}
0.18	1.6×10^{-1}	-9.1	3×10^{-1}

Since the Curie-like term in Eq. (2) does not contribute to the ^{89}Y NMR shift, one can confidently use the data for K to derive reliable information on the gap-related term. The best fit of the data for $T \leq 150$ K [solid line in Fig. 2(a)] yields $\Delta_K = 102 \pm 5$ K, in agreement with Δ_{NS} . The measurements of K are particularly useful in the doped samples, where the increase in the Curie term prevents reliable estimates of Δ and A from bulk susceptibility. From the data in Fig. 2(b) one derives $\Delta_K = 98 \pm 10$ K for $x = 0.06$ (the large error is due to the lack of data for $30 \text{ K} \leq T \leq 80$ K, see caption). The susceptibility measurements can be used to derive the x dependence of C and θ [Eq. (2)]. By assuming that A and Δ_K do not change dramatically with doping (as indicated by K), reliable fittings of χ below 100 K yield the results reported in Table I. It is noted that for $x = 0.06$ the value for the number n of $s = 1/2$ paramagnetic sites for Ni ion, is compatible with the model of three paramagnetic moments for each heterovalent substitution.¹³ The departure for $x = 0.18$ is an obvious consequence of the breakdown of the assumption of dilute magnetic moments.

The relaxation rates in pure YBNO, down to $T \approx 40$ K, are well fitted by a law of the form $T_1^{-1} \propto (-\Delta/T)$ (Fig. 3, inset) typical of gapped systems. One derives a field-independent gap $\Delta_{T_1} = 250$ K, of the order of the one expected for a dominant contribution to the relaxation involving staggered process.¹⁴

In doped compounds an extra contribution to the relaxation rate is observed in the temperature range 50–250 K, yielding a broad maximum in T_1^{-1} for $T \approx 150$ K (Fig. 3). The occurrence of novel spin excitations upon heterovalent substitutions is more evident in the divergence of the spin-spin relaxation rate T_2^{-1} (Fig. 4). In the following we qualitatively discuss these features in the ^{89}Y relaxation, by referring to a simple model of fluctuating effective field $h^e(t)$ at the Y site, that we attribute to extra magnetic moments induced by the hole along the chain. Then

$$\frac{1}{T_1} = \frac{\gamma^2}{2} \int e^{-i\omega_L t} \langle h_z^e(0) h_z^e(t) \rangle dt, \quad (3a)$$

$$\frac{1}{T_2} = \frac{1}{2T_1} + \frac{\gamma^2}{2} \int \langle h_z^e(0) h_z^e(t) \rangle dt. \quad (3b)$$

If one tentatively assumes for the components of $h^e(t)$ an exponential correlation function, with an effective correla-

tion time τ_e of the form $\tau_0 \exp[E/T]$, then the T_1 data in doped compounds, in the temperature range $50 \leq T \leq 250$ K, can be approximately fitted with $\tau_0 = 3 \times 10^{-10}$ s and $E \approx 580$ K (solid line in Fig. 3). It is interesting to observe that the holes contribution to T_1^{-1} seems to be only little dependent on x for $x \geq 0.06$. From the maximum in T_1^{-1} at $T_m \approx 150$ K, that occurs when $\tau_e \approx \omega_L^{-1}$, one can estimate $\langle |h_e|^2 \rangle$ at the Y site. One has $\sqrt{\langle |h_e|^2 \rangle} \approx 30$ G, about 30% of the intrinsic linewidth.

One can try to discuss the temperature dependence of T_2 (Fig. 4) by assuming $\langle |h_z^e|^2 \rangle \approx \langle |h_\pm|^2 \rangle$ and for $\int \langle h_z^e(0) h_z^e(t) \rangle dt$ the same correlation time τ_e used for T_1 . As it appears in Fig. 4 the behavior of T_2^{-1} is far from being fitted by this theoretical prediction. The discrepancy indicates that the spectral density of the spin excitations in the doped compounds cannot be taken of the form $J(\omega) = 2\tau_e / (1 + \omega^2 \tau_e^2)$. The results for T_2 point out that $J(\omega)$ is structured, with a central peak centered at $\omega \approx 0$, superimposed on the diffusive contribution of width τ_e^{-1} . This is a typical feature of systems characterized by nonlinear dynamics, e.g., in strongly anharmonic double-well potential, as widely discussed at structural phase transitions.¹⁵ In some cases the width of the correspondent central peak can be written¹⁶ in terms of the static correlation length and of an average velocity of propagation of solitonlike excitations. Then a divergence in T_2^{-1} can be expected, while T_1 is controlled by the regular diffusive component of the spin dynamics.

Exchange and Film Hard Magnets

R. W. McCallum, Chairman

Coercivity and exchange coupling in PrCo:Co nanocomposite films

J. P. Liu,^{a),b)} Y. Liu,^{c)} and D. J. Sellmyer^{b)}*Center for Materials Research and Analysis, University of Nebraska, Lincoln, NE 68588*

Magnetic hysteresis and intergrain exchange coupling in nanostructured PrCo:Co composite films have been investigated. The composite thin films were made by multilayer sputtering and subsequent annealing. It is found that the coercivity mechanism is related to film morphology, especially the Co phase fraction. Evidence for the hard-soft-phase exchange coupling has been found and high energy products have been obtained. © 1998 American Institute of Physics. [S0021-8979(98)26011-7]

I. INTRODUCTION

Theoretical calculations have predicted giant energy products in exchange-coupled nanostructured hard-soft-phase composites.^{1,2} However, it is difficult to obtain an ideal nanostructure experimentally. Grain growth during heat treatment and distribution of the second phases cannot be controlled and tailored easily. In addition, it is found that coercivity usually decreases dramatically as the soft phase is added. Among various methods of making nanostructured composites, physical vapor deposition has advantages in controlling grain size and distribution of second phase. We have obtained clear evidence of intergrain exchange coupling and remanence enhancement in SmCo/Co multilayer³ and FePt-based nanocomposites.^{4,5} In a recent investigation,⁶ we have successfully inserted the soft Co phase into the hard hexagonal PrCo phase thin films to enhance the remanent magnetizations without losing coercivity within a certain thickness of the Co layers. However, the domain structure remained unclear and direct evidence of exchange coupling was not found. In this investigation we study the grain morphology, domain structure, coercivity mechanism, and exchange-coupling behavior in the PrCo:Co nanocomposite films (In this article we use notation PrCo/Co to represent the as-deposited multilayers and PrCo:Co the composites after annealing.)

II. EXPERIMENT

The PrCo/Co multilayer thin films with Cr underlayer and cover layer were prepared with a multiple-gun dc- and rf-sputtering system by depositing the targets onto glass or silicon substrates. The PrCo target was made by compressing Co and Pr powders with the atomic ratio 7:2 and sintering at 1050 °C for 1 h. Flowing high-purity argon gas was used for sputtering and the pressures were varied from 5 to 20 mTorr. The sputtering parameters in this investigation (including the

argon pressure, the power rates of sputtering targets, and the distance between the targets and the substrates) were chosen to produce films with maximum coercivity. The thickness of each film was calculated by measuring the mass gain upon deposition. The as-deposited films were then heat treated in a furnace with vacuum 6×10^{-7} Torr at temperatures up to 500 °C.

Magnetization loops were measured by an alternating gradient force magnetometer and a superconducting quantum interference device (SQUID) magnetometer. Magnetic force

microscopy (MFM) and atomic force microscopy (AFM) were used to observe the domain structures and the surface morphology. More details about the crystal structure and anisotropy of the films are given in Ref. 6.

III. RESULTS AND DISCUSSION

Figure 1 shows the AFM image of nanostructured PrCo:Co grain morphology (a) and the MFM image of the domain pattern (b). It can be seen that the average size of a domain is about ten times larger than an average grain size (about 20 nm, consistent with our early TEM observation),⁶ indicating that in one domain, many grains are included. As discussed in our previous study,⁶ the PrCo:Co composite consists of the PrCo grains with a disordered hexagonal

FIG. 3. EDX spectra of a heat treated PrCo:Co film. (a) from the matrix grain and (b) from the second phase grain.

structure and elemental Co with the hexagonal close-packed structure. It is important to note that Co grains have much smaller grain size than the PrCo grains because the Co layers are much thinner than the PrCo layers when the multilayers were sputtered. The grain size we observe in Fig. 1 is basically for the matrix PrCo grains. According to theoretical calculation,² for effective intergrain exchange coupling the dimension of the soft phase should not be bigger than twice that of the domain-wall thickness of the hard phase. In rare-earth transition-metal compounds, the typical thickness of domain walls is 3–5 nm. Therefore if the grain size of the soft phase is less than 10 nm, effective intergrain exchange coupling should exist. The grain size of Co phase in the annealed samples can be controlled by controlling the Co layer thickness in the multilayers. This has been demonstrated in our previous experiments.⁶ The critical point is how to deal with the trade-off between coercivity and remanent magnetization as the amount of soft phase is increased. To optimize the energy product the effect of the soft phase on coercivity must be investigated.

Figure 2 shows the initial magnetization curves and the hysteresis loops of a group of samples with decreasing Co layer thicknesses from sample a to sample d. It is interesting to see the change of the initial magnetization curves. For sample a with multilayer structure (PrCo30 nm/Co11 nm) \times 10, the initial curve is similar to that expected in a nucleation-type mechanism of coercivity; whereas for sample d with multilayer structure (PrCo30 nm/Co5 nm) \times 10, the initial curve is typical for wall-pinning controlled reversal. However, in case of nanoscale morphology, one may have to consider interaction domains,^{7,8} because simple nucleation and pinning models might not adequate for describing the coercivity mechanism. A study of the details of coercivity mechanism is underway and will be reported later. One point clearly seen from Fig. 2 is that the increase in thickness of the soft Co layers, therefore the Co phase fraction in the annealed samples has changed the magnetization-reversal process.

It is also seen from Fig. 2 that with increasing concentration of Co phase, squareness of the loops become smaller and so does the coercivity. The change in the squareness is associated with a change in the film's morphology and the

FIG. 4. The demagnetizing curve $M(H)$ and the remanence curve $M_r(H)$ of an annealed sample (PrCo30 nm/Co8 nm) $\times 10$.

coercivity mechanism. It has been found in our experiment that the squareness and the coercivity is also strongly dependent on heat treatment. In the as-deposited films, the PrCo layer is amorphous which is magnetically soft. Heat treatment produces the magnetically hard hexagonal phase and the coercivity reaches its maximum at heat treatment temperature of 500 °C for a half-hour annealing. In order to minimize grain growth during the heat treatment, rapid thermal processing has been adopted in this investigation with heating rates up to 100 °C/s. It is found that a two-step treatment is better than a single-step treatment in obtaining greater squareness and coercivity.

Another important feature observed from Fig. 2 is that in all the cases, the ratio of remanence M_r to saturation M_s (M_r/M_s) is larger than 0.5. This is an indication that there is intergrain exchange interactions between the grains, as discussed in Ref. 6. To verify that the exchange coupling takes place between the soft phase and the hard phase, we checked the nanostructure by TEM with energy dispersive x-ray (EDX) spectroscopy and by measuring remanence curve to see the exchange-spring behavior. Figure 3 shows the EDX spectra measured in a film in two adjacent grains. One is the matrix grain (a) and another is the soft-phase grain (b). Except for Cr peaks which are from the cover layer and bottom layer and a trace of Si and C which may be from the substrate and the contamination during the specimen preparation, in (a) we detected Co and Pr elements, and in (b) we only detected Co. This shows clearly that there are two phases, the hard PrCo phase and soft Co phase existing in the composite. No third phase has been found. Figure 4 shows

the remanent magnetization curve $M_r(H)$ (also called as dc-demagnetization curve) and the demagnetizing curve $M(H)$ (the part in the second quadrant of the hysteresis loop) of a heat-treated sample. The flatness of the upper curve is equivalent to the behavior Kneller and Hawig¹ demonstrated for the exchange-spring magnets.

With the understanding of morphology and properties of the PrCo/Co composite films discussed above, we have been able to optimize the sputtering and the heat-treatment processes. We added up to 25% Co into the composite which leads to enhanced remanent magnetization without losing coercivity significantly. By a carefully controlled processing, we have succeeded in obtaining films with coercivity as high as 20 kOe and maximum energy products as high as 25 MGOe at room temperature.

IV. CONCLUSION

Magnetization behavior of PrCo:Co composite films has been studied including the initial curves and hysteresis loops. The results show that increasing the amount of soft phase appears to change the coercivity mechanism from wall-pinning-like to nucleation-like. It is also found that the coercive force and the shape of the loops are very sensitive to heat treatment. Compared with any single-step treatment, a combination of two or more steps in the heat treatment can raise coercivity markedly and improve the squareness of the loops. Optimizing the heat treatment and composite nanostructure leads to high energy products.

Nanostructured NdFeB films processed by rapid thermal annealing

M. Yu,^{a),b)} Y. Liu,^{c)} S. H. Liou,^{a)} and D. J. Sellmyer^{a)}

Center for Materials Research and Analysis, University of Nebraska, Lincoln, Nebraska 68588-0113

Nanostructured NdFeB films were prepared by magnetron sputtering followed by rapid thermal annealing at a ramp rate of 200 °C/s. Isotropically oriented Nd₂Fe₁₄B crystallites were formed in the films and coercivities up to 20 kOe and remanence ratios up to 0.8 were obtained. Transmission electron microscopy analysis shows that the majority phase of the magnetic layer in the high coercivity films consists of Nd₂Fe₁₄B nanocrystallites with an average size of about 50 nm. These nanocrystallites are believed to be single-domain particles, which are responsible for the high coercivities. MFM measurements show that the domain size is about 500 nm. It is thus indicated that the 50 nm Nd₂Fe₁₄B nanocrystallites are strongly exchange-coupled into the 500 nm domains and the high remanence ratio originates from this exchange coupling. © 1998 American Institute of Physics. [S0021-8979(98)44111-2]

I. INTRODUCTION

Since the discovery of Nd₂Fe₁₄B in 1984,¹⁻³ numerous studies on NdFeB-based materials have been conducted to obtain a better understanding of their excellent intrinsic properties and develop better fabrication processes for permanent magnets.⁴ Most of this research was on bulk NdFeB materials and relatively only a little work has been done on thin film NdFeB materials.⁵⁻¹³ With the rapid development of micromechanical devices, microelectronics, and integrated magnetoelectronic devices, applications of permanent magnet films are becoming more significant. Furthermore, better knowledge of NdFeB films also can help one to understand the exchange coupling in nanostructured magnetic materials because films thickness and grain sizes can be controlled to some extent to test some recent theoretical calculations.^{14,15}

In this article we report our systematic study of the magnetic properties of nanostructured NdFeB films prepared from amorphous state by rapid thermal annealing (RTA). RTA features a very high ramp rate (200 °C/s) and thus is able to anneal films for a very short effective annealing time (tens of seconds), which is essential in forming isotropic nanostructured NdFeB films with high coercivities (H_c) and high remanence ratios (M_r/M_s).

II. EXPERIMENTAL METHODS

All NdFeB films were deposited directly onto water-cooled 7059 glass substrates at room temperature by dc magnetron sputtering with base pressure of better than 3×10^{-7} Torr and Ar pressure of 10 mTorr. The NdFeB layer has a thickness of 500 nm and is protected by a 40 nm Cr overcoat. The Nd₁₅Fe₇₇B₈ target was provided by Electron Energy Company and some Nd chips were added to adjust the Nd concentration. The composition of the films is Nd₃₀Fe₆₃B₇, which was estimated by the area ratio of Nd chips and the target and verified by energy-dispersive x-ray measurements. The as-deposited films were all processed by

RTA technique (unless specified otherwise) in flowing Ar with a ramp rate of 200 °C/s. The structure and microstructure were characterized by x-ray diffraction (XRD) and transmission electron microscopy (TEM) measurements. The magnetic properties at room temperature were determined by a SQUID magnetometer and the magnetic domain size was estimated by MFM measurements.

III. RESULTS AND DISCUSSION

The XRD pattern of an as-deposited NdFeB film is shown in Fig. 1. Magnetic measurements showed that the as-deposited films are magnetically soft. It is thus indicated as expected that the as-deposited films are amorphous except for the presence of a little α -Fe. Figure 1 also shows the XRD pattern of the NdFeB film annealed at 500 °C for 60 s. Nd₂Fe₁₄B crystallites were formed and they were found to be isotropically oriented in the annealed film, as indicated by the peaks in Fig. 1. In fact all properly annealed films (i.e.,

FIG. 1. X-ray diffraction patterns of as-deposited and annealed (500 °C, 60 s) NdFeB films. The standard diffraction patterns of α -Fe and Nd₂Fe₁₄B phases are also shown for comparison.

^{c)}Department of Mechanical Engineering.

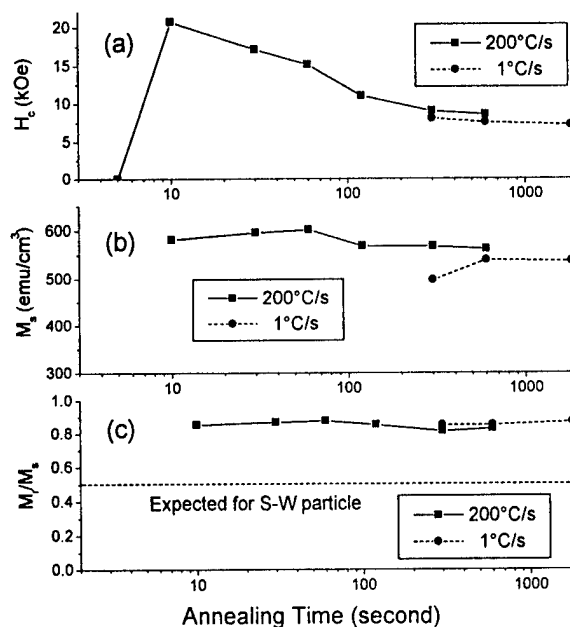

FIG. 2. TEM picture of a NdFeB film annealed at 500 °C for 60 s.

those with $H_c > 5$ kOe) consist of isotropically oriented $\text{Nd}_2\text{Fe}_{14}\text{B}$ crystallites, as confirmed by both XRD and magnetic measurements (see later discussion).

The XRD pattern of the annealed NdFeB film has peaks other than those of $\text{Nd}_2\text{Fe}_{14}\text{B}$. They can all be indexed to Nd_2O_3 and NdO phases. The oxygen was mainly introduced in the RTA process which in our case can be done only in flowing Ar.

The formation of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase is only one necessary condition to have high H_c and M_r/M_s in NdFeB films. The other is that appropriate microstructure must be developed. Figure 2 is the bright field TEM picture of the NdFeB film annealed at 500 °C for 60 s. Electron diffraction analysis indicates that the grains shown in Fig. 2 are $\text{Nd}_2\text{Fe}_{14}\text{B}$ crystallites. The size of these crystallites is about 50 nm. This means that these nanocrystallites are single-domain particles because the critical single-domain particle diameter of

FIG. 3. Hysteresis loops of NdFeB films annealed for 60 s at various temperatures (T_a).FIG. 4. (a) H_c , (b) M_s , and (c) M_r/M_s of NdFeB films annealed at 550 °C for various times with ramp rates of 200 and 1 °C/s.

$\text{Nd}_2\text{Fe}_{14}\text{B}$ is about 300 nm.⁴ The composition of the film indicates that there should be a thin Nd-rich layer between the nanocrystalline $\text{Nd}_2\text{Fe}_{14}\text{B}$ particles, although it cannot be seen due to limited resolution. The high ramp rate may also introduce some defects other than the Nd-rich layer.

With the change of structure and microstructure in Nd-Fe-B films, the magnetic properties are also changed completely after annealing. Figure 3(d) shows the parallel and perpendicular hysteresis loops of the NdFeB film annealed at 500 °C for 60 s. The large H_c (~ 16 kOe) and the similarity of the two loops also indicate the formation of isotropically oriented $\text{Nd}_2\text{Fe}_{14}\text{B}$ nanocrystallites in a Nd-Fe-B system. In addition to the formation of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase, the microstructure (the 50 nm nanocrystallites and the associated defects) also plays an important role in developing high H_c .

Annealing temperature (T_a) and time (t_a) can strongly affect the magnetic properties. Figure 3 shows the hysteresis loops of the NdFeB films annealed for 60 s at various T_a . We observed that no H_c can be developed if $T_a < 500$ °C. After T_a reaches 500 °C, H_c is developed but decreases and the saturation magnetization M_s changes slightly as T_a increases. If $T_a > 650$ °C, H_c decreases sharply with a moderate increase of M_s . These results have the following implications. First, the crystallization of $\text{Nd}_2\text{Fe}_{14}\text{B}$ can occur only when $T_a \geq 500$ °C, which is less than 627 °C, the crystallization temperature of $\text{Nd}_2\text{Fe}_{14}\text{B}$.⁴ This is reasonable because the crystallization temperature decreases when Nd concentration increases.¹⁶ Second, when $T_a > 500$ °C, presumably the $\text{Nd}_2\text{Fe}_{14}\text{B}$ nanocrystallites grow and the defects are reduced. This is the most probable reason for the decrease of H_c with the increase of T_a . Finally when $T_a \geq 650$ °C, most Nd is oxidized and α -Fe is left as the main magnetic phase, causing the sharp decrease of H_c and the increase of M_s .

Another batch of NdFeB films was annealed at 550 °C for various t_a and the resulting H_c , M_s , and M_r/M_s are

FIG. 5. MFM image of a thermally demagnetized NdFeB film annealed at 500 °C for 60 s. The CoCr MFM tip was magnetized parallel to the sample surface.

plotted in Fig. 4. It is noted that t_a has a strong effect on H_c but a weak one on M_s . Short t_a is critical to obtain high H_c , but $t_a < 10$ s is too short to achieve the proper crystallization of Nd₂Fe₁₄B for high H_c . When $T_a > 500$ °C, longer t_a has essentially the same effect as higher T_a on the microstructure, i.e., the Nd₂Fe₁₄B nanocrystallites grow and the defects are reduced. In turn H_c decreases and M_s changes slightly as t_a increases. The general effects of T_a and t_a on H_c are in agreement with the results obtained in melt-spun NdFeB materials.¹⁶

For comparison we also annealed the as-deposited films at 550 °C in a conventional oven with a ramp rate of 1 °C/s. The resulting H_c , M_s , and M_r/M_s are also shown in Fig. 4. Because of the low ramp rate, the total effective annealing time of the conventional oven is longer than that of RTA for the same t_a . Thus the H_c obtained by the conventional oven is smaller than that obtained by RTA. This result clearly demonstrates the importance of high ramp rate when very short annealing time is needed.

We have shown that the Nd₂Fe₁₄B nanocrystallites are isotropically oriented in the annealed films. According to Stoner–Wohlfarth theory¹⁷ such a system should have a M_r/M_s of 0.5 if there is no interaction among the Nd₂Fe₁₄B nanocrystallites. But Fig. 4(c) shows that these isotropic NdFeB films have $M_r/M_s > 0.8$. The high M_r/M_s must come from the strong exchange coupling among the Nd₂Fe₁₄B nanocrystallites. This phenomenon was observed in melt-spun isotropic NdFeB materials¹⁸ and predicted in theoretical

calculations.¹⁹ A MFM image of a thermally demagnetized NdFeB film annealed at 500 °C for 60 s is shown in Fig. 5. It can be estimated that the domain size is about 500 nm. This means that in one domain there are many Nd₂Fe₁₄B nanocrystallites aligned by exchange coupling. Such a micromagnetic structure (sometimes called “an interaction domain”) provides a direct explanation for the high M_r/M_s . The exchange coupling here is so strong that M_r/M_s is changed slightly when H_c is changed dramatically.

IV. CONCLUSIONS

By using the RTA technique we are able to fabricate isotropic nanocrystalline NdFeB films with high H_c and high M_r/M_s . H_c is very sensitive to annealing temperature and time. Low temperature and short time, which are just enough to crystallize the amorphous NdFeB into single-domain Nd₂Fe₁₄B nanocrystallites, are critical to obtain the proper microstructure for high H_c . We also found that these high coercivity, nanocrystalline NdFeB films have very high M_r/M_s , which originates from the strong exchange coupling among the Nd₂Fe₁₄B nanocrystallites.

$(\text{Co}_{1-x}\text{Fe}_x)\text{Pt}$ films were grown on a glass substrate by a rf sputtering and then annealed at 650–700 °C in a high vacuum. All the as-sputtered $(\text{Co}_{1-x}\text{Fe}_x)\text{Pt}$ films deposited below 400 °C had a disordered structure and showed very low coercivities. With increasing the deposition temperature and Fe contents, the (111) texture was weakened in as-deposited $(\text{Co}_{1-x}\text{Fe}_x)\text{Pt}$ ternary films. Vibrating sample magnetometer and x-ray diffraction data show that Co atoms in the $L1_0$ CoPt phase were substituted with Fe atoms. In-plane coercivities of these films decreased almost linearly with increasing Fe content which seemed to be due to the decrease of a crystalline anisotropy energy. © 1998 American Institute of Physics. [S0021-8979(98)31211-6]

I. INTRODUCTION

FePt and CoPt binary alloy films with a tetragonal $L1_0$ structure have received a significant attention because of their very high crystalline anisotropy, and thus their potential as magnetic or magneto-optic recording materials.^{1–4} Because both compounds have a tetragonal $L1_0$ structure substitution of Co atoms with Fe atoms or vice versa can give interesting properties. However, no experimental data about these ternary alloy films have not been published yet.

In this article we deposited $(\text{Co}_{1-x}\text{Fe}_x)\text{Pt}$ thin films by sputtering, annealed at 650–700 °C in a high vacuum, and investigated their magnetic and structural properties.

II. EXPERIMENTAL PROCEDURE

All films were prepared on Corning 7059 glass substrates using a rf magnetron sputter system from 10 cm diam sources at 100 W with a source to substrate distance of 6 cm. For CoPt and FePt binary films, Co–Pt or Fe–Pt composite targets were used, for which 5×10 mm Pt sheets were placed on an erosion track of pure Co or Fe targets, respectively. 100–300 nm thick $(\text{Co}_{1-x}\text{Fe}_x)\text{Pt}$ films were deposited from Co–Fe–Pt composite targets, for which additional 5×10 mm Fe or Co sheets were placed on preset Co–Pt or Fe–Pt binary composite targets. The chamber base pressure was better than 6×10^{-7} Torr and sputtering pressure was 1 mTorr. Deposition temperature was room temperature, 300 and 400 °C for the films which were deposited from Co–Pt composite targets. Films using Fe–Pt composite targets were deposited at room temperature. As-sputtered films were annealed in a high vacuum better than 7×10^{-6} Torr at 650 and 700 °C for 0.5 and 1 h. For the structural analysis, x-ray diffraction was performed on a Philips X'Pert-MPD diffractometer with a thin film attachment and Cu K_α radiation source. Film compositions were analyzed by energy disper-

sive spectroscopy (EDS). Magnetic properties were investigated by a vibrating sample magnetometer (VSM), with a maximum field of 10 kOe.

III. RESULTS AND DISCUSSION

Normally films deposited at low temperatures show a fiber texture with a close packed plane parallel to the film plane while films deposited at high temperatures show a texture with a low index plane parallel to the film plane. Because disordered CoPt films have a face centered cubic system, CoPt films deposited at room temperature showed the (111) texture and higher deposition temperatures weakened the (111) texture. Figure 1 shows x-ray diffraction patterns of CoPt binary films deposited at different temperatures. With increasing the deposition temperature well developed (111) textures became weaker and (200) and (311) peaks were clearly seen.

Figure 2 shows x-ray diffraction patterns of $(\text{Co}_{0.72}\text{Fe}_{0.28})\text{Pt}$ thin films deposited at different temperatures. Compared with Fig. 1 of CoPt binary films, the (111) texture became apparently weak and the (220) texture was devel-

FIG. 2. X-ray diffraction patterns of $(\text{Co}_{72}\text{Fe}_{28})\text{Pt}$ ternary alloy films deposited at different temperatures.

oped with the addition of Fe. Also the (220) texture was shown in $(\text{Co}_{0.72}\text{Fe}_{0.28})\text{Pt}$ films deposited at high temperatures. In Figs. 1 and 2 there were no peaks related to superlattices such as (001) and (003) peaks, meaning the formation of a disordered structure below 400 °C deposition temperature leads to very low coercivities.

Figure 3 shows x-ray diffraction patterns of $(\text{Co}_{1-x}\text{Fe}_x)\text{Pt}$ films deposited at 400 °C and annealed at 700 °C for 1 h. With increasing Fe content almost all peaks of fundamental as well as (001) superlattice peaks were clearly seen. When Fe atoms are added to the $L1_0$ CoPt structure, there would be two possibilities for phase formation. One possibility is the formation of the $L1_0$ FePt structure and another is the substitution of Co atoms with Fe atoms. If a mixture of the CoPt and FePt structure existed, there would be two peaks diffracted from (222) planes of each phase which are around 1.1° apart from each other. In Fig. 3 there are single (222) diffraction peaks and no hints of the superposition of two peaks. Therefore it can be con-

FIG. 3. X-ray diffraction patterns of $(\text{Co}_x\text{Fe}_{1-x})\text{Pt}$ films deposited at 400 °C and annealed at 700 °C for 1 h.

FIG. 4. Variation of lattice constants of ordered $(\text{Co}_{1-x}\text{Fe}_x)\text{Pt}$ films with Fe content.

cluded that Co atoms in the $L1_0$ CoPt structure were substituted with Fe atoms, thus leading to an ordered structure. It can also be seen that (111) texture becomes weaker with increasing Fe content.

Figure 4 shows the variation of lattice constants of ordered $(\text{Co}_{1-x}\text{Fe}_x)\text{Pt}$ films with Fe content. CoPt binary data were fitted because there were only (111) and (222) peaks diffracted from the same plane as shown in Fig. 3. The c/a ratio decreased with increasing Fe content, which also excluded the possibility of the mixture of the $L1_0$ CoPt and FePt phases.

Figure 5 shows the variation of in-plane coercivities of ordered $(\text{Co}_{1-x}\text{Fe}_x)\text{Pt}$ films deposited at different temperatures and annealed at 700 °C for 1 h. With increasing Fe content coercivities of all films decreased linearly. The reason for the decreased coercivity seems to be associated with the decrease of anisotropy energy, reversal mechanism change, or crystallographic texture change. It seems that there is no possibility of the reversal mechanism changing because both in-plane and perpendicular coercivities of films were almost the same, suggesting the spin rotation mecha-

FIG. 5. Dependence of Fe contents on the coercivity of $(\text{Co}_{1-x}\text{Fe}_x)\text{Pt}$ films.

FIG. 6. Dependence of Co content on coercivities of $(\text{Co}_x\text{Fe}_{1-x})\text{Pt}$ films.

nism. Effects of the texture on the coercivity should be excluded because films deposited at different temperatures and annealed had almost the same coercivities even though the degree of the (111) texture is quite different. Therefore the decrease of coercivities in Fig. 5 seems to be due to the decrease of anisotropy energy.

Figure 6 shows the coercivities of $(\text{Co}_{1-x}\text{Fe}_x)_{0.55}\text{Pt}_{0.45}$ films sputtered from the Fe–Pt composite target for which Pt and Co sheets were placed on a pure Fe target. The binary film had an equiatomic composition while Pt contents of ternary films were 4–6 at % lower than that of the stoichiometric FePt phase. In Fig. 6 coercivities decreased rapidly with increasing Co content. The ordered FePt $L1_0$ phase has been known to be formed in a wide Pt range of 22–50 at %.⁵ We tried to find superlattice peaks of $(\text{Co}_{1-x}\text{Fe}_x)_{0.55}\text{Pt}_{0.45}$ films, but it was very difficult to analyze it by x-ray diffraction (XRD) because of a high degree of the (111) texture as shown in Fig. 7. In Fig. 7 there was a very broad peak around $2\theta = 24^\circ$, but the peaks seemed to be unrelated to the superlattice (001) peak because same broad peaks could be observed in as-sputtered films. Further, if we consider the results of Figs. 4 and 5, and Ref. 5, the possibility for forming the ordered $(\text{Co}_{1-x}\text{Fe}_x)_{0.55}\text{Pt}_{0.45}$ phase was very low.

FIG. 7. X-ray diffraction patterns of $(\text{Fe}_{1-x}\text{Co}_x)_{0.55}\text{Pt}_{0.45}$ films annealed at 650°C for 1 h.

These are very unexpected results; the reason is not clear yet and more experimental results are needed.

IV. CONCLUSION

$(\text{Co}_{1-x}\text{Fe}_x)\text{Pt}$ films were grown on a glass substrate by a rf sputtering and then annealed at $650\text{--}700^\circ\text{C}$ in a high vacuum. All as-sputtered $(\text{Co}_{1-x}\text{Fe}_x)\text{Pt}$ films deposited below 400°C had a disordered structure and showed very low coercivities. With increasing deposition temperature and Fe content, the (111) texture was weakened in as-deposited $(\text{Co}_{1-x}\text{Fe}_x)\text{Pt}$ ternary films. Vibrating sample magnetometer (VSM) and x-ray diffraction pattern data show that Co atoms in the $L1_0$ CoPt phase could be substituted with Fe atoms. In-plane coercivities of these films decreased almost linearly with increasing Fe content which seemed to be due to the decrease of crystalline anisotropy energy.

Angle-dependent x-ray magnetic circular dichroism (XMCD) experiments performed at both the Co and Pt $L_{2,3}$ edges for a cubic CoPt₃ thin film, which exhibits growth-induced chemical anisotropy, are used to determine the element specific magnetic anisotropy. The large decrease of the 3d orbital moment, observed when the spins are forced out the easy axis of magnetization by the applied magnetic field, is a consequence of a strong magnetocrystalline anisotropy (MCA). In addition, a weak but systematic variation of the Pt orbital moment indicates that the 5d atoms could play an important role in the MCA. These results correlate the microscopic XMCD evaluation of the MCA and the local structural anisotropy as observed with x-ray absorption fine structure (XAFS).

© 1998 American Institute of Physics. [S0021-8979(98)53911-4]

Compared to classical bulk methods, alloy growth by the ultrahigh vacuum evaporation methods such as molecular beam epitaxy (MBE) benefits of surface diffusion controlled by an appropriate choice of temperature growth and deposition rates. It is an appealing route to "fabricate" materials with specific properties, and is of prime importance for the development of magnetic and magneto-optic materials. In this respect, Co_xPt_{1-x} thin alloy films, that are characterized by large Kerr rotations at short wavelengths and strong magnetocrystalline anisotropy (MCA), appear as good candidates to substitute the current TbFeCo media.¹ Recently, strong perpendicular magnetic anisotropy (as large as 10^7 erg cm⁻³) as well as 100% perpendicular remanence has been observed in (111)-oriented fcc CoPt₃ alloy films.^{2,3} This was unexpected for a cubic lattice and was attributed to the existence of an anisotropic local chemical order.³ MCA is known to be a microscopic effect,⁴ but the evidence of MCA comes mainly from macroscopic measurements (either torque or magnetization).^{2,3} To demonstrate unambiguously the correlation between MCA and this growth-induced chemical anisotropy, angle-dependent x-ray magnetic circular dichroism measurements (XMCD) were performed at both the Co and Pt $L_{2,3}$ edges. XMCD is obviously a good probe to provide new information: the sum rules for XMCD⁵ show a correlation between orbital momentum and MCA through separate spin and orbital magnetic moment evaluations.⁶ In addition, the site selectivity of XMCD allows one to investigate the role of the Pt orbital moment in the MCA: this role has not yet been considered, although calculations argue that the

large anisotropy observed in Co-Pt or Co-Pd systems results mainly from the large spin-orbit interaction on the 5d (4d) atoms.⁷

The (111) CoPt₃ thin film alloy was deposited by MBE in a 10^{-10} Torr pressure onto a 150 Å Ru (0001) buffer layer grown at 900 K onto a mica (001) substrate. The 500 Å thick film was co-evaporated at 690 K using deposited rates of 0.2 Å/s for Pt and 0.05 Å/s for Co, respectively. Finally a 15 Å protective Pt layer was deposited. The film exhibits a fcc disordered structure, slightly compressed along the growth direction [111].³ Such a deformation was attributed to an anisotropic local order, which was confirmed by XAFS measurements performed at the Co K and Pt L_3 edges, revealing the existence of preferential CoPt pairs along the growth direction.⁸ This structural anisotropy is mainly the result of two effects: (i) the surface diffusion which at 690 K is large compared to the bulk mobility, and (ii) the Pt surface segregation during deposition. This film may be seen as surface alloys stacked above each other and frozen-in as the free surface advances. Finally, this surface chemical ordering yields an anisotropic alloy with a large MCA. The magnetization hysteresis loops show an easy axis of magnetization perpendicular to the film plane (i.e., the [111] direction) with roughly $K_u = (1 \pm 0.2)10^7$ erg cm⁻³ at 30 K. It is worth noting that the growth temperature is the key parameter in fabricating such systems, since a completely disordered fcc film grown at room temperature and a L1₂-type ordered fcc film grown at 800 K do not exhibit perpendicular anisotropy.³

XMCD experiments were carried out at the ESRF beamlines ID 12A (Pt $L_{2,3}$ edges) and ID 12B (Co $L_{2,3}$ edges). The straight section ID 12 is equipped with two helical un-

FIG. 1. Normalized XMCD signal measured in the total electron yield detection mode at the Co $L_{2,3}$ edges for a CoPt₃ thin film alloy ($\gamma=60^\circ$). In the inset the result of the integration of the XMCD signal is shown [i.e., $3L_z/2n_h$ (in units of \hbar)] for $\gamma=30^\circ$, 45° , and 60° , respectively.

dulators (Helios-I and Helios-II) which cover two complementary energy ranges from soft (0.5 to 1.6 keV) to hard (3.0 to 22.0 keV) x rays.^{9,10} Helical undulators provide a highly circular polarization rate, which is well transferred by the optical elements for the two present investigations, and allow to alternate easily the helicity of the photons. For the energy range requested for the Pt $L_{2,3}$ edges (11.0–13.5 keV), the third harmonic of the undulator Helios-II was chosen and the double-crystal monochromator was equipped with a pair of Si (111) crystals. For the measurements at the Co $L_{2,3}$ edges, the ID 12B branch was equipped with a grating spectrometer (1200 1/mm). The circular polarization rate was estimated to be 0.9 (ID 12A) and 0.85 (ID 12B), respectively. The XAS spectra were recorded at room temperature (i) in the fluorescence detection mode, using a Si photodiode associated with a digital lock-in exploiting square waves modulated x-ray beam, for the measurements at the Pt $L_{2,3}$ edges, and (ii) in the total electron yield detection (TEY) mode for the measurements at the Co $L_{2,3}$ edges. For both experiments, the XMCD signal was monitored by keeping the helicity of the incoming x rays fixed and flipping the direction of the applied magnetic field generated by a superconducting magnet (± 4 T, i.e., parallel or antiparallel to the direction of the incoming light). No sizable self-absorption effect is expected using the fluorescence mode at the Pt $L_{2,3}$ edges since the film is very thin with respect to the penetration depth of the incoming photons; and to avoid saturation effects in the measurements performed at the Co $L_{2,3}$ edges (TEY mode), the analysis has been restricted to $0^\circ < \gamma < 60^\circ$, where γ denotes the angle between the direction of the incoming light (i.e., the direction of the applied magnetic field) and the normal to the surface. Let us emphasize that due to the small absorption coefficient of the 500 Å CoPt₃ film (about 3% at the Pt $L_{2,3}$ edges), these experiments were rather challenging.

Co $L_{2,3}$ edges

Figure 1 shows a typical XMCD spectrum recorded in the TEY mode at $\gamma=60^\circ$. The XMCD signal is normalized to the isotropic absorption cross section (i.e., approximately,

FIG. 2. $-L_z/n_h$ (in units of \hbar) as a function of the incident angle γ . The full curve represents the fitting assuming that the 3d orbital moment varies (at lowest order) as $m_{\text{orb}}^\perp + (m_{\text{orb}}^\parallel - m_{\text{orb}}^\perp) \sin^2 \gamma$, where m_{orb}^\perp and m_{orb}^\parallel denote, respectively, the orbital moment measured along and perpendicular to the [111] direction.

the half-sum of the absorption cross section recorded for left- and right-handed circularly polarized light) corresponding to the $2p-3d$ transitions and is corrected for the finite rate of circular polarization. Using the notation of Arvanitis *et al.*,¹¹ the angle-dependent orbital sum rule for XMCD takes the form:

$$m_{\text{orb}}^\gamma = -(2Q^\gamma/3)(10 - n_{3d}), \quad (1)$$

where m_{orb}^γ is the orbital moment measured at the angle γ , n_{3d} is the number of electrons in the 3d shell and Q^γ is the normalized integrated dichroism intensity at the angle γ . The

FIG. 3. Upper panel: $L_{2,3}$ isotropic absorption edges of Pt in a CoPt₃ thin alloy film (500 Å) and of Au (dashed line) in a CuAu₃ bulk sample. Lower panel: difference between the spectra recorded for left- and right-circular polarized light (XMCD signal). The XMCD is corrected for the rate of circular polarization.

magnetic field was sufficient to saturate the magnetic moment, so no additional data corrections are needed.

According to (1), the integral Q^γ of each XMCD signal shown in the inset of Fig. 1 is directly proportional to the orbital moment. The drastic diminution of the orbital moment when the spins are forced out of the [111] direction by the 4 T applied magnetic field is the microscopic signature of strong MCA.¹² In the case of a uniaxial anisotropy, it has been found that the 3d orbital moment varies (at lowest order) as $m_{\text{orb}}^\perp + (m_{\text{orb}}^\parallel - m_{\text{orb}}^\perp) \sin^2 \gamma$, where m_{orb}^\perp and m_{orb}^\parallel denote, respectively, the orbital moment measured along and perpendicular to the easy axis of magnetization (i.e., the normal to the surface).⁴ Figure 2 shows the good agreement between our experiments and this theoretical prediction (full curve) supporting the present model. Taking 7.75 for the 3d electron occupation number,¹³ we found $m_{\text{orb}}^\perp - m_{\text{orb}}^\parallel = 0.13 \mu_B$ and $m_{\text{orb}}^\perp = (0.30 \pm 0.02) \mu_B$. This enhancement of the orbital moment [the value measured for bulk hcp Co [0001] is $m_{\text{orb}}^\perp = 0.15 \mu_B$ (Ref. 14)] is consistent with previous XMCD experiments that have found an obvious connection between orbital moment, MCA and the breaking of symmetry at interfaces.^{14,15}

Pt $L_{2,3}$ edges

According to calculations, the strong MCA observed in Co-Pt (Pd) systems is the consequence of the strong 5d (4d) spin-orbit coupling ($\xi_{\text{Pt}}/\xi_{\text{Co}} \approx 8$):⁷ roughly speaking, the 3d atoms would play a minor role in the MCA, acting only as a "source of magnetism." We recently found in Pd/Co multilayers an anisotropy of the 4d orbital moment of $m_{\text{orb}}^\perp - m_{\text{orb}}^\parallel = 0.07 \mu_B$, which demonstrates the important role played by the 4d atoms in the MCA.¹⁶ Figure 3 shows the isotropic absorption and the corresponding XMCD signal recorded in the fluorescence detection mode at the Pt $L_{2,3}$ edges. The XMCD signal is corrected for the incomplete polarization of the x rays and the applied magnetic field was tilted at 30° away from the normal to the surface. To separate the transitions to unoccupied 5d states from the continuum ($2p \rightarrow nd, s$), a steplike function (or an arctangent function) can be subtracted from the isotropic absorption cross section. This procedure has been extensively used for the determination of the 3d near-edge resonance (the "white line"); however the L_3 and L_2 Pt edges do not exhibit a strong white line and the errors in the determination of the steplike background, negligible for the $L_{2,3}$ Co edges, might now be as large as 40%. For an accurate analysis, we have compared the L_3 and L_2 Pt edges with those of Au, measured in a CuAu₃ bulk alloy under the same experimental conditions. The energy scale of the Au spectra was expanded with a factor 1.07 to account for the difference in the lattice parameter, aligned in energy with the Pt spectra on the fine structure and finally normalized to the edge jump.¹⁷ According to this procedure, the angle-dependent orbital sum rule takes the following form:

$$m_{\text{orb}}^\gamma = -2(\Delta A_{L_3}^\gamma + \Delta A_{L_2}^\gamma) \times \{3[\sigma_{\text{tot}}(\text{Pt}) - \sigma_{\text{tot}}(\text{Au})]/[n_{5d}(\text{Pt}) - n_{5d}(\text{Au})]\}^{-1}, \quad (2)$$

where $\Delta A_{L_3}^\gamma$ and $\Delta A_{L_2}^\gamma$ are the integrals over the dichroism at the L_3 and L_2 edges, respectively, $\sigma_{\text{tot}}(\text{Pt}) - \sigma_{\text{tot}}(\text{Au})$ is the integral of the isotropic absorption cross section over the difference curve and $[n_{5d}(\text{Pt}) - n_{5d}(\text{Au})]$ is the electron number difference, calculated to be 1.06.¹³ The application of the sum rule gives $m_{\text{orb}} = 0.052, 0.049$, and $0.044 \mu_B$ for $\gamma = 30^\circ, 45^\circ$, and 60° , respectively. Despite the uncertainties in the determination of the orbital moment (typically 10%), it appears that the anisotropy of the 5d orbital moment exists. Reminding that the MCA energy is proportional to the spin-orbit constant, the anisotropy of the Pt orbital moment itself, as weak as it may be, should also play an important role in the MCA.

Angle-dependent XMCD experiments at the Co and Pt $L_{2,3}$ edges in a fcc (111) CoPt₃ thin film give evidence for a strong correlation between the chemical anisotropic local order and the MCA. In agreement with previous experiments, we found a large anisotropy of the 3d orbital moment ($m_{\text{orb}}^\perp - m_{\text{orb}}^\parallel = 0.13 \mu_B$) and have confirmed the validity of the model developed by Bruno,⁴ who has shown theoretically that the 3d orbital moment varies as $m_{\text{orb}}^\perp + (m_{\text{orb}}^\parallel - m_{\text{orb}}^\perp) \sin^2 \gamma$ for a uniaxial symmetry. Thanks to the high quality of the data recorded, we were able to measure a weak but systematic decrease of the 5d orbital moment when the spins are forced out of the easy direction. These findings support the idea that the 5d orbital moment itself could play an important role in the MCA.

Magnetic properties of NdFeB thin films synthesized via laser ablation processing

ChoongJin Yang,^{a)} SangWon Kim, and Jong Seog Kang

Electromagnetic Materials Laboratory, Research Institute of Industrial Science & Technology (RIST),
P.O. Box 135, 790-600 Pohang, Korea

High energy product $\text{Nd}_2\text{Fe}_{14}\text{B}$ films have been grown onto Si(100) substrate by KrF pulsed laser ablation using the targets of $\text{Nd}_x\text{Fe}_{90.98-x}\text{B}_{9.02}$ ($x = 17.51-27.51$). The films exhibit no preferred texture, however, good hard magnetic properties were produced from as-deposited condition: $4\pi M_s \approx 7$ kG, $4\pi M_r \approx 4$ kG, and $H_c = 300-1000$ Oe. The beam density of 3 J/cm^2 gave the optimal condition to have the highest $4\pi M_r$ and H_c for a substrate T of 650°C . The higher content of Nd induces a higher coercivity and $4\pi M_r$ at the same time without prominent change in $4\pi M_s$. The films grown at elevated temperature ($620-700^\circ\text{C}$) are understood to suggest a magnetically coupled interaction between $\text{Nd}_2\text{Fe}_{14}\text{B}$ and $\alpha\text{-Fe}$ grains by taking into account the monotonously decreasing $4\pi M_r$ values accompanying with a broad peak regime in H_c at around $550-625^\circ\text{C}$.

If high field strength permanent magnets in film forms can be easily synthesized, those film magnets can then be used to fabricate integrated electromagnetic components. Circulators and isolators are the typical hybrid type microwave devices using the ferrite disks for a biasing field. Magnetoresistive heads are another area in which permanent magnetic films can play a significant role to obtain the magnetoresistive sensitivity. Miniaturized magnetic sensors, actuators, and motors are other areas that can benefit from the development of film type magnets.

In spite of these expectations the magnetic field strength of the films must be comparable to the energy product term in bulk magnets. In addition hard magnetic films in microdevices and data storage technology must be cost effective, yet produces smooth hard magnetic films with high values of $4\pi M_s$, $4\pi M_r$, and H_c . Furthermore, a popular film substrate, such as Si wafer, must be proven to be an appropriate material showing no mismatch with the magnetic film materials for volume production in future. Nd-Fe-B compounds of suitable composition and nanostructure is a good candidate for the above requirements. NdFeB magnetic films have been studied during the past years by sputtering a cast target.¹⁻⁴ Recently, a high coercive NdFeB films grown on MgO(100) by molecular beam epitaxy (MBE) was reported.⁵

In this article we report a laser ablation technique for synthesizing $\text{Nd}_2\text{Fe}_{14}\text{B}$ base films using a KrF excimer laser. Our interest is on controlling the microstructure in nanoscale to obtain a high field strength films which presumably will consist of magnetically coupled soft and hard grains.

The magnetic films were prepared by a KrF excimer laser (248 nm wave) ablation. The lasing energy density ranged from 2.75 to 5.99 J/cm^2 at a constant repetition rate of 10 Hz was employed using $\text{Nd}_x\text{Fe}_{90.98-x}\text{B}_{9.02}$ ($x = 17.5-27.5$) targets. The films were deposited onto Si(100) wafer at various substrate temperatures ranging $620-700^\circ\text{C}$. Targets were made by induction arc melting and repeated

homogenization treatment. The film thickness was controlled by total pulse of $2500-3000 \text{ \AA}$ for all the samples which exhibited an optimal magnetic properties. The average deposition rate was identified after pulsation for ten minutes for each lasing condition, and the thickness was checked by the scanning electron microscope and "α-Step" as well.

Characterization was performed as functions of various ablation parameters such as laser beam density, Nd contents of targets and substrate temperatures. The film samples were pulsed to have about 300 nm thick with a rate of 10 Hz . As the lasing beam density increases linearly from 2.75 to 5.99 J/cm^2 , the deposition rate of film varied linearly from 0.038 to 0.13 nm/s .

Figure 1 shows the typical magnetic properties as a function of beam energy density. The target composition was

FIG. 1. Laser beam energy dependency on the magnetic properties of $\text{Nd}_{27.51}\text{Fe}_{63.47}\text{B}_{9.02}$ film on (100)Si deposited at a substrate temperature of 680°C .

^{a)}Electronic mail: cjyang@risnet.rist.re.kr

FIG. 2. TEM micrographs and electron diffraction patterns of $\text{Nd}_{27.51}\text{Fe}_{63.47}\text{B}_{9.02}$ films deposited at a laser beam energy density of (a) 3.08 J/cm^2 and (b) 5.99 J/cm^2 , respectively, at 680°C .

$\text{Nd}_{27.51}\text{Fe}_{63.47}\text{B}_{9.02}$, and the film was grown at 680°C . The open circles denote data measured along the in-plane, and the solid circles for out-of-plane direction. The experimentally saturated magnetic moments ($4\pi M_s$) along parallel direction ranged about 5300–5700 G, while those of 1000 G lower values were exhibited along the out-of-plane direction. Saturation magnetization was found to be almost constant regardless of the laser energy density. However, remanence values along the out-of-plane were measured to be much higher for laser energy density $2.75\text{--}3.08 \text{ J/cm}^2$ as shown in Fig. 1(b). The numbers in round brackets, which are reduced remanence (M_r/M_s) values, for the samples grown with the laser energy density of $2.75\text{--}3.08 \text{ J/cm}^2$ are at most $0.5\text{--}0.52$. The laser energy density higher than 3.5 J/cm^2 gave poor shape of hysteresis curves resulted in low values of both the $4\pi M_r$ and H_c . Although the magnetic properties of the films decrease with higher beam densities, the microstructure of all films indicated the presence of $\text{Nd}_2\text{Fe}_{14}\text{B}$ without any minor phase clarified by x-ray diffraction (XRD) and TEM. Only the difference in the microstructure between the films at lower (3.08 J/cm^2) and higher beam density (6.0 J/cm^2) is the grain size as shown in Fig. 2. The grain size of $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase of the film at a higher beam density (6.0 J/cm^2) is measured to be doubled (36 nm) that of film at 3.08 J/cm^2 .

Figure 3 shows the variation of magnetic properties as a function of substrate temperature (T_s) for the films grown at a laser beam density of 3.08 J/cm^2 . For $T_s < 640^\circ\text{C}$, the hysteresis behaves like a soft magnet which shows $4\pi M_r \leq 330 \text{ G}$ and $H_c \leq 180 \text{ Oe}$. If T_s is raised above 640°C , however, both the $4\pi M_r$ and H_c increase resulting from a very coercive hysteresis curve, and the M_r/M_s becomes more than 0.5 . X-ray pattern indicated that T_s below 640°C let the films largely amorphous without any minor phase. One interesting thing regarding the substrate temperature is that the

FIG. 3. Substrate temperature dependency on the magnetic properties of $\text{Nd}_{27.51}\text{Fe}_{63.47}\text{B}_{9.02}$ film on (100)Si deposited at a laser beam energy density of 3.08 J/cm^2 .

deposition rate of film was found to be more than 0.6 Å/s below 640°C , while above that temperature the rate was less than 0.5 Å/s .

The variation of $4\pi M_r$ and H_c depend strongly upon the concentration of Nd of the targets. Figure 4 shows the magnetic properties of $\text{Nd}_x\text{Fe}_{90.98-x}\text{B}_{9.02}$ films grown at T_s of 680°C with the beam density of 3.08 J/cm^2 . The variation of $4\pi M_s$ as a function of Nd content is low along the both in-plane and out-of-plane directions. However, the $4\pi M_r$ and H_c exhibit different behaviors. The films grown from the targets of $x = 17.51$ and 22.51 shows the M_r/M_s along in-

FIG. 4. The effect of Nd content on the magnetic properties of $\text{Nd}_x\text{Fe}_{90.98-x}\text{B}_{9.02}$ films on (100)Si deposited at the substrate temperature of 680°C at a laser density of 3.08 J/cm^2 .

plane of 0.51–0.55, and along out-of-plane of 0.14–0.18 with a low value of $4\pi M_r$ and H_c as well. For the films $x = 27.51$, however, the $4\pi M_r$ and H_c along out-of-plane change abruptly to have $M_r/M_s = 0.52$ and $H_c = 900$ Oe, respectively. X-ray diffraction patterns of $x = 17.51$, 22.51, and 27.51 clearly show that the spectrum of lower Nd contents indicates the poor formation of $\text{Nd}_2\text{Fe}_{14}\text{B}$ crystallite, while the pattern of $x = 27.51$ shows well developed crystallites. In spite of the variation of Nd content the films formed at T_s of 620–680 °C consist of single phase of $\text{Nd}_2\text{Fe}_{14}\text{B}$, while the films grown at room temperature to indicate the presence of amorphous and crystalline. The previous studies on NdFeB films processed by sputtering^{1,3,4,6} exhibited the anisotropic texture aligning the c axis perpendicular to the film plane.

The high-resolution micrographs of the films $\text{Nd}_{17.51}\text{Fe}_{73.47}\text{B}_{9.02}$ and $\text{Nd}_{27.51}\text{Fe}_{63.47}\text{B}_{9.02}$, respectively, indicate that the basic difference between those Nd concentrations is the grain size. The films of Nd=27.51 at. % shows the finer grains less than 15 nm of $\text{Nd}_2\text{Fe}_{14}\text{B}$ which resulted in a higher coercivity than those of Nd=17.51 or 22.51 at. % whose grain size was found to be around 20 nm. In the course of ablation around the eutectic temperature some excess of Nd might oust out of the alloy, and the formation of Nd-rich grainboundary would take place to anchor the motion of magnetic domains.

Figures 5(a) and 5(b) shows the typical variations of magnetic properties of $\text{Nd}_{17.51}\text{Fe}_{73.47}\text{B}_{9.02}$ films grown at room temperature and 680 °C, respectively. The data were for the samples measured along in-plane direction taking into account the applicability of the film type permanent magnets exhibiting the high field strength along the in-plane direction of the end devices. In Fig. 5(a) both the $4\pi M_s$ and $4\pi M_r$ of as-deposited films are high due to the presence of abundant amorphous phase which also shows the lower coercivity. By post annealing at *in situ* substrate the $4\pi M_r$ values drop prominently to a certain value (4000 G) and then stabilized thereafter. Almost the same behavior is denoted for $4\pi M_s$. As was mentioned above the post annealing seems to induce the fusion of Nd and oust out the grain boundaries. However, as the annealing temperature is increased, the H_c value enhances considerably up to 600 Oe around 600–650 °C. The formation of $\text{Nd}_2\text{Fe}_{14}\text{B}$ crystallites developed by crystallizing amorphous phase appears to be responsible for the enhancement of H_c . At higher temperatures, H_c decreases due to the extended growth of $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains. The above rationalization for the magnetic properties seems to also be true for the films grown at 680 °C in Fig. 5(b).

The high values of $4\pi M_s$ and $4\pi M_r$ for the as-deposited films grown at 680 °C tend to decrease with increasing the annealing temperature. At the same time, H_c values increase to the maximum value (550 Oe) around 550–600 °C and then decrease thereafter [Fig. 5(a)]. In this case, it should be understood that if the film samples exhibit the

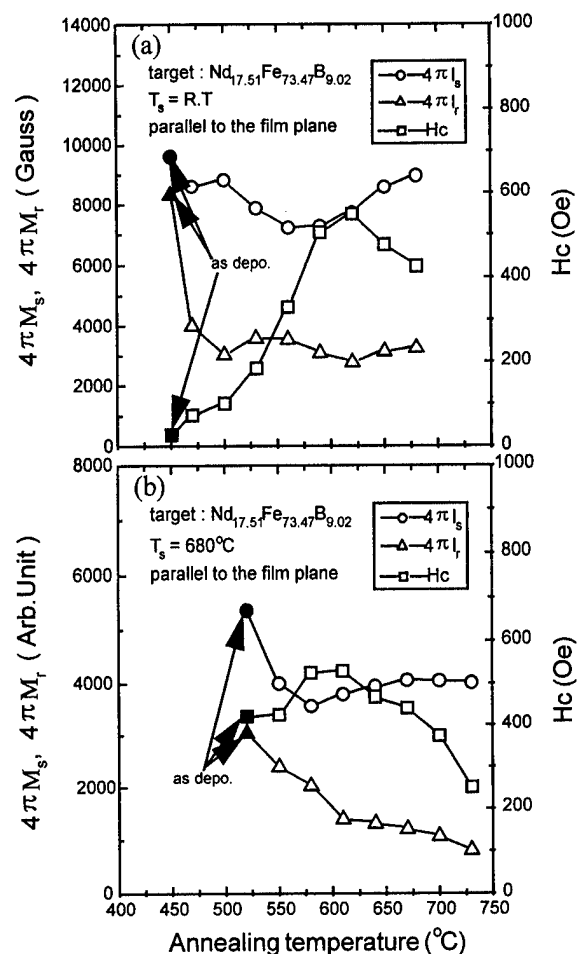

FIG. 5. The variation of magnetic properties as a function of annealing temperature for $\text{Nd}_{17.51}\text{Fe}_{73.47}\text{B}_{9.02}$ films deposited at (a) room temperature and (b) 680 °C.

same demagnetization effect at each temperature, the decreasing $4\pi M_r$ should be accompanied with decreasing H_c values due to the slender hysteresis curve. In addition, the $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains developed during the previous temperature regime will grow, losing their coercivity. However, in Fig. 5(b) H_c still shows a broad maximum over a small temperature range. These films indicate a coupling interaction between $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains and magnetically soft $\alpha\text{-Fe}$ grains which inevitably will form during post annealing.

Maximum energy product of isotropic Nd-Fe-B-based nanocomposite magnets

J. Kuma, N. Kitajima, Y. Kanai, and H. Fukunaga

Department of Electrical Engineering and Computer Science, College of Engineering, Nagasaki University, 1-14 Bunkyo, Nagasaki 852 Japan

The maximum energy products, $(BH)_{\max}$, of isotropic Nd-Fe-B-based nanocomposite magnets were calculated by a three dimensional model ($10 \times 10 \times 10$) that incorporated non-uniform magnetization reversals by subdivisions of the grains. Based on the results of our simulation, the largest obtainable $(BH)_{\max}$ for a sample with 60% soft and 40% hard grains is about 290 kJ/m^3 . This value is lower than the previous crude estimate of 400 kJ/m^3 but is almost twice as large as the experimental measured maximum of 160 kJ/m^3 suggesting that further improvement in $(BH)_{\max}$ is possible if the nanostructure of an actual magnet can be made close to the theoretically ideal structure.

© 1998 American Institute of Physics. [S0021-8979(98)44211-7]

I. INTRODUCTION

In developing isotropic Nd-Fe-B nanocomposite magnets, it is important to obtain the maximum energy product, $(BH)_{\max}$, that is close to the theoretical upper bound. Based on numerical calculations, the theoretically obtainable $(BH)_{\max}$ of those magnets were estimated to be around 400 kJ/m^3 .^{1,2} On the contrary, experimentally measured $(BH)_{\max}$ have not exceeded 160 kJ/m^3 .³ Part of the difference may be caused by the two-dimensional nature of the model² or by the suppression of nonuniform magnetization reversals.¹ Hence we have attempted to improve the estimate of $(BH)_{\max}$ by subdividing the grains to incorporate nonuniform magnetization reversals while maintaining the three-dimensional configuration of the grains.

After the effects of the subdivision were studied and 64 elements per grain was found to be sufficient for accurate calculation of $(BH)_{\max}$, the calculation was repeated with $n=64$ to investigate the theoretically ideal nanostructures. The ratio of soft and hard grains and a relative exchange strength were varied and the conditions for the maximum $(BH)_{\max}$ were obtained.

II. SIMULATION MODEL AND METHOD

Our simulation model is shown in Fig. 1. 1000 magnetically soft and hard cube-shaped grains were arranged in an array of $10 \times 10 \times 10$. Periodic boundary conditions are used in three directions to eliminate the necessity of demagnetizing-field correction. After the fractions of the magnetically soft and hard grains were specified, the locations of the grains were determined by pseudorandom numbers. The magnetically hard grains represent Nd-Fe-B with a uniaxial anisotropy constant, $K_u^{(H)} = 4.5 \times 10^6 \text{ J/m}^3$ and saturation magnetization $M_s^{(H)} = 1.61 \text{ T}$. Moreover, their easy axes are randomly distributed in space to model an isotropic material. The magnetically soft grains are assumed to be iron with no anisotropy ($K_u^{(S)} = 0$) and saturation magnetization $M_s^{(S)} = 2.16 \text{ T}$.

In order to study the effects of nonuniform magnetization reversals, all the grains were subdivided into $n=1, 8,$

27, or 64 cubic elements. The magnetization inside each element is assumed to be uniform, but this scheme allowed to approximate nonuniform magnetization reversals within the grain.

The total energy W of the magnet, when an external field \mathbf{H} is applied, is given by

$$W = - \sum_{i=1}^{n \times 1000} \left\{ K_{ui} \frac{V}{n} (\mathbf{u}_i \cdot \mathbf{m}_i)^2 + \frac{J_e S}{6n^{2/3}} \left(\sum_{j=1}^6 \mathbf{m}_i \cdot \mathbf{m}_j \right) + M_{si} V (\mathbf{m}_i \cdot \mathbf{H}) \right\} + W_m, \quad (1)$$

where the terms in the brackets represent the anisotropy energy, the exchange interaction energy caused by the six neighboring elements and the applied field energy in that order. W_m represents the magnetostatic energy due to the local demagnetization field.

K_{ui} and M_{si} are the anisotropy constant and the saturation magnetization of the i th element, and their values de-

FIG. 1. Model of a magnet.

pend on the kind of grain in which the element is located. S and V are the surface area and the volume of each grain and are converted into those of each element by dividing by n or $n^{2/3}$, where n is the number of elements per grain. J_e is the exchange interaction constant per unit surface area, and a single value was assumed for all the boundaries.

\mathbf{u}_i is a unit vector in the direction of the easy axis of the i th element. \mathbf{m}_i and \mathbf{m}_j are the magnetizations in the i th and the j th elements and are reduced by the saturation magnetization of the corresponding grain.

To find the directions of the magnetizations in response to an applied field, the following form of Gilbert's equation⁴ is numerically integrated.

$$\frac{d\mathbf{m}_i}{dt} = \frac{\gamma}{(1 + \alpha^2)M_{si}V} \mathbf{A} \frac{\delta W}{\delta \mathbf{m}_i}, \quad (2)$$

$$\mathbf{A} = \begin{pmatrix} \alpha(\beta_{ix}^2 - 1) & \alpha\beta_{ix}\beta_{iy} - \beta_{iz} & \beta_{iy} + \alpha\beta_{iz}\beta_{ix} \\ \beta_{iz} + \alpha\beta_{ix}\beta_{iy} & \alpha(\beta_{iy}^2 - 1) & \alpha\beta_{ix}\beta_{iy} - \beta_{iz} \\ \alpha\beta_{ix}\beta_{iy} - \beta_{iz} & \beta_{ix} + \alpha\beta_{iy}\beta_{iz} & \alpha(\beta_{iz}^2 - 1) \end{pmatrix}$$

where γ and α are the gyromagnetic constant and the damping parameter, respectively. β 's are the direction cosines of the magnetization in the i th element so that $\mathbf{m}_i = (\beta_{ix}, \beta_{iy}, \beta_{iz})$.

The variation of the total energy with respect to \mathbf{m}_i can be written as

$$\frac{\delta W}{\delta \mathbf{m}_i} = -2K_u^{(H)} \frac{V}{n} \left\{ \frac{K_{ui}}{K_u^{(H)}} \mathbf{u}_i (\mathbf{u}_i \cdot \mathbf{m}_i) + \frac{J_e S n^{1/3}}{6K_u^{(H)} V} \left(\sum_{k=1}^6 \mathbf{m}_k \right) + \frac{M_{si}}{2K_u^{(H)}} (\mathbf{H} + \mathbf{H}_{di}) \right\}. \quad (3)$$

Here the ratio of the exchange energy to the anisotropy energy of a magnetically hard grain, $J_e S / 6K_u^{(H)} V$, is defined as the exchange parameter η . The calculated magnetic properties depend solely on η and the fraction of the soft grains once K_u and M_s of two kinds of grains are specified.

\mathbf{H}_{di} is the local demagnetizing field acting on the i th element and is calculated in the following manner. First, we calculate the distribution of the magnetic charges according to the magnetization of each element. These results are used to calculate the magnetic potential by means of FFT (fast Fourier transform) and the inverse FFT. \mathbf{H}_{di} is calculated as the gradient of the magnetic potential at the i th element.

After the directions of the magnetizations were determined, the reduced magnetization m of the model is calculated as the sum of the in-field component of $\mathbf{M}_i (= M_{si} \mathbf{m}_i)$ divided by the sum of the saturation magnetizations of all the elements.

III. RESULTS

In order to examine the effects of the subdivisions of the grains, five different configurations of 60% soft and 40% hard grains were generated with $\eta = 0.118$, and the simulation was repeated. The value of η and the fraction of the soft grains were so selected that the largest $(BH)_{\max}$ was obtained for a single cubic element.

FIG. 2. Demagnetization curves for magnets containing 60% soft grains.

Figure 2 shows the calculated demagnetization curves that were close to the average of those five simulations. In the figure, h is the reduced applied field defined as $h = H / (M_s^{(H)} / 2K_u^{(H)})$. As the number of elements in a grain, n , is increased, the remanence, m_r , decreases and approaches 0.8. At the same time the hysteresis loops deviate more from a square loop.

The directions of the magnetizations are shown in Fig. 3 for $n=27$ with a reversal field of $|h|=0.055$ applied in the negative x direction. A cross-sectional plane parallel to the x - y plane was selected, and the magnetizations of the grains contained in that plane were projected onto the x - y plane. The darker arrows represent the magnetizations in magnetically hard elements and lighter arrows represent those in the soft elements. The directions of magnetizations in the hard grains are relatively uniform, because their anisotropic en-

FIG. 3. Directions of magnetizations projected onto x - y plane. $h = -0.055$ is applied to a sample containing 60% soft grains. Each darker arrow represents the magnetization in a magnetically hard element, and a lighter arrow represents the magnetization in a soft element. ($n=27$).

FIG. 4. Dependence of $(BH)_{\max}$ on the number of elements in a grain. The average value and the range of $(BH)_{\max}$ of 5 simulations are shown at each n .

ergy is about 9 times larger than the exchange energy. The magnetizations in the soft grains, on the other hand, show non-uniform behavior because of the lack anisotropy.

Figure 4 shows the dependence of $(BH)_{\max}$ on the number of elements per grain. As n increases, the calculated $(BH)_{\max}$ decreases and approaches about 250 kJ/m^3 . The range of $(BH)_{\max}$ also diminishes as expected.

The calculation of $(BH)_{\max}$ was repeated for $n=64$ with various ratios of soft and hard grains and a range of η . As shown in Fig. 5, the largest $(BH)_{\max}$ was observed when the ratio of the soft grains was 60%, which was same as the case of $n=1$. When n was increased from 1 to 64, however, the the largest $(BH)_{\max}$ increased from 250 to 290 kJ/m^3 and the corresponding values of η shifted from 0.118 to a larger value (or a smaller grain size). If we assume $J_e = 16 \times 10^{-2} \text{ J/m}^2$, $\eta=0.177$ corresponds to the optimum grain size of 20 nm.

IV. CONCLUSIONS

The magnetic properties of isotropic Nd-Fe-B-based nanocomposite magnets were calculated by computer simulation based on a micromagnetic theory. Each grain was subdivided into 1 to 64 elements to study the effects of nonuniform magnetization reversals within the grain. As the number of elements per grain increased, both the calculated

FIG. 5. $(BH)_{\max}$ as a function of the exchange interaction parameter η with the ratio of the soft grains varying from 40 to 75%. The grain sizes are calculated assuming $J_e = 1.6 \times 10^{-2} \text{ J/m}^2$.

$(BH)_{\max}$ and m_r decreased and approached constant values. Thus $n=64$ appears to be sufficient for an accurate estimate of $(BH)_{\max}$.

The simulation was repeated by varying the exchange interaction parameter η and the fraction of the soft grains. The largest $(BH)_{\max}$ was obtained when the ratio of the soft grains was 60% as reported before. However, the value of $(BH)_{\max}$ obtained with $n=64$ was 290 kJ/m^3 . This value is about 28% lower than the previous estimate of 400 kJ/m^3 . It was also noted that the largest $(BH)_{\max}$ corresponded to a grain size of 20 nm which is smaller than the estimate made without non-uniform magnetization reversals.

The remaining difference between the experimentally measured maximum $(BH)_{\max}$ of 160 kJ/m^3 and this simulation is probably caused by the differences in the nanostructures. In other words the magnetic properties may be further improved by fabricating magnets whose nanostructures are closer to the theoretically ideal structures.

Remanence enhancement in mechanically alloyed isotropic Nd(Fe, Mo)₁₂N_x compounds

Yiaofu Xiao,^{a)} Qi Zeng, Shengzhi Dong, and Run Wang

Institute of Materials Science and Engineering, University of Science and Technology, Beijing 100083, People's Republic of China

The structure and magnetic properties of Nd(Fe, Mo)₁₂N_x compounds prepared by mechanical alloying have been studied using x-ray diffraction, transmission electron microscopy, and magnetic measurements. After heat treatment and nitriding, it is found that almost single-phase Nd(Fe, Mo)₁₂N_x can be obtained. Electron microscopy revealed a nanometer grain size of 10–30 nm and the magnets have a remanence enhancement of approximately 60% of the saturation.

I. INTRODUCTION

In structurally isotropic magnetic materials the ratio of remanent magnetization M_r and saturation magnetization, M_r/M_s , is at 0.5.¹ Recently enhanced magnetically isotropic properties have been observed in single-phase materials^{2,3} and two-phase materials containing both hard and soft magnetic phase. In these materials, M_r is significantly greater than $1/2M_s$. As to single-phase materials, there are two necessary conditions for the remanent enhancement phenomenon happening:² (1) a substantial absence of an intergranular phase between the crystallites, and (2) a specific grain size range.

Due to a relatively high Curie temperature, high saturation magnetization and a large (easy *C* axis) anisotropy field, Nd(Fe, M)₁₂N_x (M=Mo, Ti, V) compounds are promising candidates for permanent magnet application.^{4,5} Nd(Fe, Mo)₁₂N_x especially, has the advantage of easy formation of its single phase and the realization of high coercivity. So in this article, we report on the occurrence of remanence enhancement in mechanically alloyed Nd–Fe–Mo–N powders.

II. EXPERIMENT

Alloys of NdFe₁₀Mo₂ compounds were prepared by induction melting of 99.9 wt. % pure materials in a water cooled crucible under purified argon atmosphere. An additional amount of Nd (3 wt. %) was added to compensate for the loss during the process. The ingots were annealed at 950 °C for 100 h. For mechanical alloying (MA), the annealed compounds were crushed into particles with a diameter of less than 50 μm and sealed into a vial with several 10 and 12 mm stainless steel balls in a ratio of powder to ball of 1 to 20 under argon atmosphere. MA was done in a high-energy ball mill designed by our laboratory for 24 h. All handling was conducted in a glove box filled with argon gas. Crystallization was carried out in the temperature range from 700 to 900 °C for 0.5 h in a vacuum atmosphere. The recrystallized compounds were nitrided at 500 °C for 2 h in pure nitrogen atmosphere. X-ray diffraction (XRD) analysis was

conducted using Cu *Kα* radiation with a Rigaku D/max-rA diffractometer equipped with a graphite crystal monochromator. Transmission electron microscope (TEM) observation was performed with an H-800 electron microscopy, and magnetic measurement was performed with a magnetometer operating in a field of 2 T.

III. RESULTS AND DISCUSSION

X-ray diffraction patterns of a mechanically alloyed NdFe₁₀Mo₂ sample are shown in Fig. 1. It can be seen from Fig. 1(a) that the mechanically alloyed materials show a mixture of amorphous and α-Fe. On subsequent isothermal aging at 1073 K, the mechanically alloyed powders were converted into Nd(Fe, Mo)₁₂ with the ThMn₁₂ structure [Fig. 1(b)]. The nitrided ThMn₁₂ crystalline structure was obtained by following nitrogenation, and it is composed of single-phase 1:12 [Fig. 1(c)].

Figure 2 show the hysteresis loop of a NdFe₁₀Mo₂N_x compound measured in a field of 2 T. The sample was crystallized at 1073 K for 0.5 h and nitrided at 773 K for 2 h. It can be seen that $M_s=70.7$ emu/g, $M_r=44.5$ emu/g, and $M_r/M_s=0.63$. However, the sample was unable to be satu-

FIG. 2. Hysteresis loop of $\text{NdFe}_{10}\text{Mo}_2\text{N}_x$ powder measured in a field of 2 T.

rated at the field of 2 T, so we use the “law of approach”⁶ to calculate the M_s for $H \rightarrow \infty$, which is approximately 75.4 emu/g and corresponding to $M_r/M_s = 0.60$.

The crystal size of the aged, MA powder was found to be approximately 15 nm by X-ray diffraction analysis. The TEM micrograph of an individual powder particle, which has the size of 300 nm, is shown in Fig. 3. It is comprised of randomly oriented equiaxed crystallites with the tetragonal ThMn_{12} structure. The crystallite size of the nanocrystalline phase ranges from 10 to 30 nm, being in good agreement with the x-ray diffraction analysis. In addition, the crystallites are substantially free of any intergranular phase—crystalline or amorphous. The employment of dark-field techniques verified that there is intimate contact between ThMn_{12} grains.

The exchange interaction tends to align all the magnetic moments parallel, and conversely the anisotropy interaction lines up the magnetic moments in each grain with its crystallographic C -axis direction. The exchange energy grows with the increasing intergrain contact surface area. On the other hand the anisotropy energy grows with increasing grain volume. Hence, at sufficiently small grain sizes accommodation between the two types of magnetic interaction arises. The remanence enhancement phenomenon results from this accommodation of the two competing interactions. The direction of each grain's magnetization deviates from its C axis towards the direction of the neighboring grains' magnetization; hence, the resultant magnetization of the entire magnet is greater than if each grain acted independently. However, the grain sizes are so small that the coercivity becomes

FIG. 3. TEM bright-field image and the corresponding diffraction pattern of MA $\text{NdFe}_{10}\text{Mo}_2$ powder which had been milled for 24 h, aged, and nitrided.

lower, only 5.0 kOe was obtained in our study, which is lower than the result reported by Gong and Hadjipanayis.⁷

IV. CONCLUSION

MA has been successfully used in the preparation of $\text{Nd}(\text{Fe}, \text{Mo})_{12}\text{N}_x$ permanent magnets with remanence enhancement, $M_r/M_s \approx 0.6$. The reasons for the exchange interaction to give rise to the magnetic enhancement are: (1) the mean grain size of 20 nm; (2) the substantial absence of any intergranular phase.

Magnetic properties of $\text{Nd}_8\text{Fe}_{77}\text{Co}_5\text{B}_6\text{CuNb}_3$ melt-spun ribbons

H. Chiriac^{a)} and M. Marinescu

National Institute of R&D for Technical Physics, 47 Mangeron Boulevard, 6600 Iasi 3, Romania

$\text{Nd}_8\text{Fe}_{77}\text{Co}_5\text{B}_6\text{CuNb}_3$ amorphous ribbons were obtained by the melt spinning method using a large range of the wheel circumferential speed (18–40 m/s). For 10 min time of heat treatment at 700 °C the following values of the magnetic characteristics were achieved: $H_c = 3.95$ kOe, $B_r = 11.25$ kG, and $(BH)_{\text{max}} = 15$ MGOe. The 13% increase of the remanent ratio $M_r/M_{1.5\text{T}}$ by applying a magnetic field during annealing suggests an improvement of the exchange coupling effect. The Curie temperature of both hard and soft magnetic component phases increases with about 50 °C due to the Co content but it is not affected by the magnetic field annealing. © 1998 American Institute of Physics. I. INTRODUCTION

The most attractive alloys which exhibit hard magnetic properties are the NdFeB based alloys. Two methods are known to produce NdFeB magnets: powder metallurgy and rapid quenching from the melt. The former leads to a microstructure that was found to consist of large grains (4–10 μm) of $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase embedded in a matrix of Nd-rich phase.¹ The main advantage of the second route is that it allows the possibility of lowering the Nd content without affecting the magnetic properties. In this case two phases are separated: a soft magnetic Fe-based phase having high saturation ($4\pi M_s = 2.2$ T) and a hard magnetic $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase having a high anisotropy constant ($K_1 = 4.3 \times 10^6$ J/m³). The properties of each individual magnetic phase contribute to the properties of the entire ensemble due to their ferromagnetic exchange coupling. The optimum hard magnetic properties are obtained when the crystallites behave as single domain ($d_g < 40$ nm) and there exist a uniform distribution of the magnetically soft and hard phases.² The nanoscale grain refinement can be obtained directly during the quenching process but in this case the presence of the metastable phases cannot be controlled,³ or from amorphous precursors by annealing. In order to obtain a “clean” magnetic structure we preferred to use the second method.

The quenchability⁴ and the nanostructured phase formation are improved by adding various elements at the basic composition. The most known addition used in soft magnetic materials is the pair of the atomic species (Cu, Nb) which promote the formation of the grains and act as a grain growth inhibitor. For this reason we studied the $\text{Nd}_8\text{Fe}_{77}\text{Co}_5\text{CuNb}_3\text{B}_6$ composition. The Co was added in order to increase the Curie temperature of the hard phase, thus enlarging the temperature range in which the magnets could be used.

We also present the influence of the magnetic field annealing on the exchange coupling between the magnetic phases evaluated in terms of $M_r/M_{1.5\text{T}}$.

II. EXPERIMENT

An alloy ingot of $\text{Nd}_8\text{Fe}_{77}\text{Co}_5\text{CuNb}_3\text{B}_6$ was prepared by arc melting pure constituents (99.9% purity). Amorphous flakes up to 20–25 cm in length and 20–25 μm in thickness were produced in an inert atmosphere by the melt spinning technique. For wheel circumferential speed of 18–40 m/s, the samples were obtained in an amorphous state. The nanocrystalline structure has been induced by annealing the samples at 700 °C for different periods of time in a range of 2–20 min. Other samples were subjected to an external applied magnetic field of 0.8 T during the same heat treatments. In order to evaluate the effect of the magnetic field annealing after each treatment the hysteresis loops were measured using a vibrating sample magnetometer (VSM), and the strength of the magnetic interactions was evaluated by means of the remanence ratio $M_r/M_{1.5\text{T}}$. The structure of both as-cast and annealed ribbons was investigated by the x-ray diffraction (XRD) method. The Curie temperatures of the hard and soft magnetic phases were pointed out by the thermomagnetic curve.

III. RESULTS AND DISCUSSION

X-ray diffraction studies performed on as-cast ribbons present a broad maximum, which is specific to the amorphous structure even using a wheel circumferential speed $v_{\text{circ}} = 18$ m/s.

Influence of the annealing time of the amorphous ribbons obtained for $v_{\text{circ}} = 26$ m/s, on coercivity, reduced remanence and maximum energy product is presented in Fig. 1. It seems that the most adequate time for heat treatment is that performed for 10 min, when the best magnetic properties of the investigated ribbons have achieved the following values: $H_c = 3.95$ kOe, $B_r = 11.25$ kG, and $(BH)_{\text{max}} = 15$ MG Oe. We applied the magnetic field during heat treatment in order to induce a uniform nucleation of the grains and thus to improve the ferromagnetic exchange coupling effect between them. The exchange distance was deduced to be of the order of about 4 nm for the hard phase and of the order of at least 40 nm for the soft Fe-based phase. If this latter distance exceeds the size of the grains, then strong interactions occur not only between the contacting hard grains but also between
